# MOLECULAR PHYSICS

BY

JAMES ARNOLD CROWTHER, Sc D

LATE FELLOW OF ST JOHN'S COLLEGE, DEMONSTRATOR IN PHYSICS  
AT THE CAVENDISH LABORATORY, CAMBRIDGE

SECOND EDITION

*WITH FORTY-NINE ILLUSTRATIONS*

LONDON

J & A CHURCHILL

7 GREAT MARLBOROUGH STREET

1919

## PREFACE TO THE FIRST EDITION

THE present volume is an attempt to give a connected account of the constitution and properties of the atom and molecule in the light which has been thrown upon these particles by recent physical research. From the great mass of experimental observations which constitute what has been called somewhat vaguely the "New Physics" I have endeavoured to select those portions which have a direct bearing on this important and fascinating subject, and I have drawn freely on all available sources of information, some of which are indicated in the Bibliography at the end of the book.

To Professor Sir J. J. Thomson I owe a debt of gratitude for his kindness in allowing me to select from his experimental negatives, and to reproduce, the Positive Ray photographs which illustrate Chapter IV. I owe him still more for the privilege which I have enjoyed during the past eight years in the Cavendish Laboratory, of moving in daily contact with much of the work, and of drinking in, as it were at the fountain head, much of the theory narrated in the present volume. To this must be ascribed any merits which the following pages may be found to possess, for their errors and deficiencies I, alone, am responsible.

J. A. C.

## PREFACE TO THE SECOND EDITION

I HAVE taken the opportunity afforded me by the appearance of a second edition of this little volume to make a complete revision of the material which it contains. In many ways the changes and additions are not as great as might have been expected. The conditions of a great war are not favourable to theoretical research, and many ingenious pieces of apparatus, which might ere now have been expected to yield important additions to our knowledge, lie covered with the dust of the laboratory awaiting the return of happier times. In some points, however, our knowledge has increased. In particular the results obtained in the laboratory of Sir Ernest Rutherford have added so materially to our knowledge of the structure of the atom that I have felt justified in adding a special chapter on this profoundly interesting subject, while the recognition by Sir J. J. Thomson of the existence of two great and markedly different classes of chemical compounds has led to such important changes in, and additions to, the theory of chemical affinity as to demand almost a complete re-writing of the chapter on the chemistry of the atom. While other changes are not numerous, every effort has been made to carry out in the case of the second edition what was the object of its predecessor, and to present a coherent and intelligible account of the present state and most recent advances in the electron theory of matter.

# CONTENTS

	PAGE
CHAPTER I — INTRODUCTION	1
Historical survey   The old and the new physics	
The molecular theory of matter   Molecular magnitudes	
CHAPTER II — THE PHYSICS OF THE ELECTRON	10
The discharge of electricity through gases	
Cathode rays   Measurement of the ratio of the mass to the charge for the cathode rays	
Measurement of the charge on an electron	
Photography of the tracks of ionising particles	
CHAPTER III — THE POSITIVE PARTICLE	34
The $\alpha$ -particles from radio-active substances	
Counting the $\alpha$ -particles   The charge on an $\alpha$ -particle   Production of helium from $\alpha$ -rays	
CHAPTER IV — THE NEW METHOD OF ANALYSIS	43
Positive particles in the discharge tube   SIR J. J. THOMSON'S experiments   Measurement of the velocity and mass of the positive particles   Positive ray analysis   The new gases   Application of the method to the study of chemical decomposition   Electrical methods of measurement	
CHAPTER V — THE NATURE AND SIZE OF AN ELECTRON	67
The Faraday tubes   Electro-magnetic mass	
Variation of electro-magnetic mass with speed	
Kaufmann's experiments on the $\beta$ -rays from radium   The radius of an electron	
CHAPTER VI — THE STRUCTURE OF THE ATOM	82
The number of electrons in the atom   The positive nucleus, its charge and size   The electrical theory of matter   The structure of the atom   The stability of groups of electrons   Cohesion and adhesion   The periodic law	

CHAPTER VII — THE ELECTRON THEORY OF VALENCY	PAGE 112
Electrolysis    Valency and the periodic law Ionised and non ionised molecules    Specific inductive capacity    Electrical conditions of stability Nature of chemical affinity	
CHAPTER VIII — THE ATOM IN VIBRATION	130
Propagation of disturbances along a Faraday tube    The wave theory of light    The Zeeman effect    Spectral series    The origin of spectra	
CHAPTER IX — THE MOLECULAR THEORY OF MATTER	150
Solids, liquids, and gases    The kinetic theory of heat    Change of state    Van der Waal's equation    The size of the atom    Electron theory of thermal and electrical conduction

## CHAPTER I

### INTRODUCTION

THE history of the rise of molecular theory has often been written. From Dalton, who first gave to the conceptions of the early atomists a definite meaning and a real experimental basis, through Avogadro and his fertile hypothesis of the molecule, and so on to the kinetic theory of Clausius and Maxwell, the story is told in almost every text-book of Chemistry and Physics, and is familiar as household words to all their readers. Here for a time science seemed to pause in her progress. It seemed as if the memoirs of these brilliant mathematicians were to contain the last word in molecular theory.

If this had been so, the following pages would have been superfluous. In the last few years, however, new fields have been opened to the student of molecular phenomena, new methods of approach have been evolved so potent in character that subjects about which we had until then barely sufficient grounds for speculation are now laid open to direct experimental attack. The molecule has been raised from a conception only realisable experimentally in millions to the rank of a definite particle whose entry into our apparatus produces a definite and measurable effect. At the same time the accuracy,

and what is still more important, the certainty, of our measurements of molecular magnitudes have been enormously increased. It seemed, therefore, neither undesirable nor devoid of interest to attempt to re-write the subject of molecular physics, not from the standpoint of the kinetic theory, by which it was approached historically, and which constituted for many years the sole line of attack, but rather in the light thrown upon these problems by the recent developments in what has come to be known as the "New Physics."

In order to fix our attention upon the problems to be dealt with, and to recall to our minds some clear ideas of the magnitudes with which we shall have to deal, it may be well to consider briefly the position to which we have been brought by the exponents of the kinetic theory.

The atom itself was a purely chemical conception. It took its rise in an attempt to explain the laws of chemical combination, and represents the smallest mass of an element which can take part in a chemical reaction. By its first exponents it was regarded as homogeneous and indivisible. This view is no longer held. We shall see later that we must conceive of the atom as something approaching a planetary system on an infinitesimal scale. A study of the phenomena of radioactivity has driven us to believe that in them we are dealing with a true decomposition of a true chemical atom, that the element radium is in fact a decomposition product of the atom of uranium, and is itself in the course of transition into an atom of lead, with the emission during the process of several atoms of helium. This break up of an atom, however, is a process which we are permitted to watch, but not to control. So far we have not succeeded in either accelerating or retarding its progress in any way whatever.

In compounds the atoms of the different elements

were supposed to be grouped together into similar particles or molecules, the ratio of the masses of the components being the same in each individual molecule as in the compound as a whole. It was soon found necessary to assume that even in the elements the atoms were usually connected into groups of two or more to form a larger particle, which, unless taking part in a chemical reaction, always moved and acted as a single system. This extension of the theory was due to Avogadro, and his additional hypothesis that the number of these molecules in a given volume of gas under similar conditions is independent of the nature of the gas was the first great generalisation in the physics of the molecule.

It was soon realised that these molecules were particles exceedingly small in size. Various attempts to determine the approximate diameter of the molecules all led to the result that it was not very much greater than  $2 \times 10^{-8}$  cms. Various illustrations have been employed to assist us to grasp the extreme minuteness of this quantity. If, for example, a drop of water were to be magnified to the size of the earth the molecules in it would be of the size of footballs. Or again, as a recent writer has suggested, we may say that the carbon atom in the printed page subtends at the reader's eye the same angle as would be subtended there by a man on the moon.

The number of molecules in any visible portion of matter is, of course, correspondingly large. According to the latest determinations the number of molecules in 1 cub. cm. of air under normal conditions ( $0^{\circ}$  C. and 760 mm. pressure) is  $2.7 \times 10^{19}$ . It is almost hopeless to attempt to conceive this inconceivable swarm of particles. It may, perhaps, be of some assistance to point out that in the highest attainable vacua, when the pressure of the gas is not more than  $\frac{1}{100000}$  mm. of mercury, the number of

molecules present in every cubic millimetre of the space still exceeds 2,000,000,000

In a solid body we must regard the molecules as relatively fixed. They are indeed in rapid vibration about their mean position, such vibration constituting the phenomenon which we know as heat. The fact that ancient gems and coins have come down to us through many ages still preserving their sharp outlines and their beautiful and clear-cut engraving shows that, in the absence of external forces, the defection of a molecule in a solid from its original station must be of exceedingly rare occurrence.

In liquids, however, we must regard the molecules as free to move. A liquid has no definite shape of its own, and two liquids if left quite undisturbed will gradually diffuse through each other with a velocity which is in general small but quite measurable. The different molecules possess sufficient energy to escape from the attraction of neighbouring systems, but move only a very short distance through the thickly-crowded space before becoming entangled in other clusters.

Gases differ from liquids in the fact that the space occupied by a given number of molecules is very much greater, and a molecule therefore travels much further before coming into collision with other molecules. Thus a gramme of water substance when transformed into steam occupies 1,600 times the volume which it had in the liquid state. The molecules are therefore  $\sqrt[3]{1,600}$  or, say, 12 times as far

apart in the gas as in the liquid. The actual volume of the molecules themselves is thus only a very small fraction of the volume filled by the gas, the molecules occupying the space between their boundaries not by filling it with their bulk, but by moving about in it in all directions with considerable velocities.

The tendency of a gas to spread through the whole of the space accessible to it thus represents the tendency of each molecule to proceed on its path in a straight line when not opposed by any obstacle, while the pressure on the boundaries of the gaseous space is due to the exceedingly rapid series of impacts made on them by the innumerable swarm of molecules in motion.

The velocity with which the molecules in a gas are moving can easily be calculated when the pressure and density are known. The mean velocity of a molecule of oxygen at the freezing point of water is about 425 metres per second, or about 1,000 miles per hour. It is, therefore, somewhat greater than the velocity of sound through air under the same conditions (331 metres per second). In addition to collisions upon the boundaries each molecule collides from time to time with other molecules of the gas, the number of collisions made by a single molecule under ordinary conditions of temperature and pressure being about 6,000,000,000 every second.

The distance travelled by the particle between two collisions is known as its free path. Its actual value between any two collisions depends, of course, upon chance. Its mean value can, however, be calculated from the viscosity of the gas. For air under ordinary conditions it is about  $7.6 \times 10^{-8}$  cms., or roughly  $\frac{1}{100,000}$  of an inch.

This mean free path, although a giant among molecular magnitudes, is still rather smaller than the smallest distance we may ever hope to perceive. Abbe has shown that two objects would have to be separated by rather more than twice this distance before they could be resolved by the best possible microscope working under the best conditions.

The mass of each molecule is, of course, exceedingly minute, according to the recent determinations of Rutherford, which we shall describe later, the

mass of a hydrogen atom is  $1.61 \times 10^{-24}$  gms., a number so minute that it can hardly be said to convey to the mind any impression at all. This number, it will be seen, represents the value in grammes of the chemical unit of atomic weight, the mass in grammes of any atom or molecule can thus be calculated from a table of atomic weights by merely multiplying the chemical atomic or molecular weight by this factor. Small as is this quantity we shall see that its value is known with certainty to within a very few per cent.

Of the quantities with which we have been dealing, the kinetic theory gave accurately the velocity of the molecule and the mean free path. It threw only a dim and somewhat uncertain light upon the number and mass of the individual molecules. As to the nature of the molecule it can hardly be said to have given any information at all. It is at once the strength and the weakness of the statistical methods employed in the kinetic theory, that given a sufficiently large number of molecules, their exact number, size, mass and properties become for many purposes matters of indifference. Thus many of the properties of gases were successfully deduced, in the first place, on the assumption that the molecule was a hard sphere, an assumption which in the case, say, of a molecule like that of oxygen built up of two atoms is almost certainly incorrect. It will be seen then how little light can be thrown upon the individual molecule by investigations of this nature.

As the molecule itself lay far beyond the limits of vision, and as the kinetic theory could afford so little certain information, it might have seemed that we must rest content with the knowledge already attained. Speculation as to the nature of the atom was not wanting, ranging from the simple hard atom of the original theory to the centre of force

of Boscovitch, and the vortex atom of Professor Thomson, the early speculation of one who has done, perhaps, more than any other to render possible a true theory of the atom. These theories, ingenious as they were, withered for lack of experimental support, and the subject became gradually to be regarded as being in the realm of the unknowable. Meanwhile the great success of the statistical methods of the kinetic theory, the extension of thermodynamics, and the study of phenomena from a consideration of their equilibrium conditions which followed on the work of Willard Gibbs, were leading further and further away from atomic and molecular hypotheses.

Fortunately one loophole remained into this region of the infinitely small. The kinetic energy of a particle is equal to the product of one-half its mass into the square of its velocity. However small the mass of the particle, therefore, we can theoretically by sufficiently increasing its velocity endow it with an appreciable amount of energy. In the case of a molecule the velocity required will, of course, be very large. The energy of a molecule in the air under normal conditions of temperature and pressure is about  $5 \times 10^{-14}$  ergs, assuming the mass and velocity already given. This is far too small to be detected. Let us suppose, however, that we can endow our molecule with a velocity much greater than this, approaching  $2 \times 10^9$  cms per second. The energy of an oxygen molecule moving with such a speed would be  $\frac{1}{2} (32 \times 1.61 \times 10^{-24}) (2 \times 10^9)^2$  ergs, or about  $10^{-1}$  ergs. This, though small, is not less than can be appreciated in other forms of energy. Thus Lord Rayleigh has estimated that the faintest sound which can be heard transmits every second across a square centimetre of area at right angles to its path about  $2.3 \times 10^{-8}$  ergs. The energy in the faintest perceptible beam of light is not far different

from this. Thus the energy of impact of a single molecule travelling with the velocity we have suggested would be comparable with the energy in a faint beam of light or a just audible sound

The velocity ascribed to the molecule in this calculation might seem impossibly large. It is in fact about  $\frac{1}{16}$  of the velocity of light, and a particle travelling with this speed would, therefore, cover the distance from the earth to the sun in 2 hours. Such particles, however, actually exist, and it is the discovery of these particles and the measurements made upon them that have led to the great advances in molecular physics which we are about to describe. Particles having this velocity are shot out in large numbers from radioactive bodies. To anticipate a little we may say that the  $\alpha$ -particles from radium consist of atoms of helium shot out with a speed of this order of magnitude, and bearing a positive charge. Thus it is that a single  $\alpha$ -particle is able to cause a flash of light when it strikes upon a screen covered with a suitable material.

The  $\alpha$ -particles consist of helium atoms only. Velocities approaching that of the  $\alpha$ -particles can be given to atoms and molecules of other substances by passing an electric discharge through them in the gaseous state at very low pressures. The phenomena of the discharge tube have indeed afforded the best means of investigating the properties of moving electrified particles, and we shall proceed to their consideration immediately.

In order to complete our survey we will anticipate so far as to say that the first experimental investigation of these phenomena led to results of a startling nature. Professor Sir J. J. Thomson, as the result of a brilliant series of researches and deductions, which may truly be said to mark a fresh era in the progress of science, showed that the most conspicuous set of particles in the discharge tube, namely, those

constituting the cathode rays, had a mass not more than  $\frac{1}{1800}$  part of that of a hydrogen atom

It was found, moreover, that whatever the nature of the gas through which the discharge was passing, whatever the nature of the electrodes used, the mass of the cathode particle produced and the magnitude of the charge carried by it was always the same. These cathode particles, corpuscles or electrons, as they came to be called, must thus be regarded as forming an integral part of the atom of every kind of substance. They are, therefore, even more fundamental than the atom itself, since they form part of the material from which the atom is built up. The methods used in their investigation are similar in principle to those which have recently been applied to atoms and molecules, but the special properties of the electrons rendered their experimental investigation less difficult than that of the atom or molecule, so that for a time it could truly be said that far more was known of the electron than of the atom itself. For these reasons we will commence our study of molecular physics with the consideration of the electron.

## CHAPTER II

### THE PHYSICS OF THE ELECTRON

THE general appearance of an ordinary discharge tube is perhaps familiar to most of my readers. It is represented somewhat diagrammatically in Fig. 1. Covering the cathode C is a velvety light known as the cathode glow. Beyond this is a comparatively dark space, named after its discoverer Sir William Crookes. If the pressure in the tube is fairly high this Crookes dark space will be so close to the cathode and so small as to be hardly visible. Beyond

FIG. 1.—THE DISCHARGE TUBE

this dark space is another luminous area, the negative glow, bounded on the side remote from the cathode by still another obscure area, the Faraday dark space. The length of the tube occupied by these phenomena depends mainly on the pressure of the gas, and is practically independent of the size of the tube, the remainder of which, however long, is filled with a bright light known as the positive column, which is frequently, though not

necessarily, divided into numerous striæ. It is the light from this positive column that is generally employed in the spectroscopic examination of gases in the discharge tube.

If the pressure is fairly low another phenomenon may be distinguished. Proceeding normally from the cathode and penetrating in straight lines across one or more of the dark spaces may be seen faint bluish streams of light, known as the cathode rays. As the pressure is still further reduced these rays become relatively more and more important, and penetrate further and further, until finally they fall upon the glass walls of the discharge tube, exciting there a greenish phosphorescence. Meanwhile the Crookes dark space has grown until it occupies practically the whole of the tube, the remaining parts of the ordinary discharge being represented by the glow on the cathode and a single patch of light near the anode itself.

The nature of the cathode rays remained for some time in doubt. However, in 1895 Perrin showed that they transported a negative charge, and in the following year Professor Sir J. J. Thomson proved conclusively that they consisted of streams of negatively charged particles, moving with extremely high velocities, and having a mass in all probability much less than that of a hydrogen atom.

Let us continue for a moment the study of the discharge tube. It had long been known that if a solid obstacle were placed in the path of the discharge a shadow of the object was cast by the cathode rays on the opposite wall of the tube. It was noticed that if the obstacle was placed within the Crookes dark space a shadow was also cast on the cathode. That is to say, there must also be rays in the tube proceeding in the opposite direction to the cathode rays and falling upon the cathode itself. By using

a perforated cathode, as shown in the diagram, these rays become visible as faintly luminous streaks of light, coming from each of the perforations, and exciting a faint mauve phosphorescence where they strike the walls of the tube. These rays, which carry a positive charge and have a mass comparable with that of an atom, are formed by the positive particles to which we have already alluded.

The high velocities of these particles give them, as we have seen, sufficient energy to produce luminous effects when they fall upon suitable screens. The additional fact that they carry an electric charge enables us to determine not only the velocity, but also the ratio of the mass of the particles to the charge which they carry.

The general problem of the motion of an electrified particle when moving under the action of electric and magnetic forces is one of some little complexity, though complete solutions have been given by various mathematicians. Fortunately the special cases which are required for our present purpose lend themselves readily to the simplest treatment.

Suppose that a particle of mass  $m$  and charge  $e$  is moving with a velocity  $v$  at right angles to a magnetic field of strength  $H$ . In one second the charge  $e$  will have moved through a distance  $v$  cms. We may therefore regard the path of the particle as a sort of conductor  $v$  cms long, carrying an electric current whose strength is  $e$ . The mechanical force on such a conductor when placed in a magnetic field is known from the laws of electro-magnetic induction to be equal to the strength of the field multiplied by the current and the length of the conductor, that is to the product  $H e v$ . Further, this force is at right angles to the direction of the current and to the lines of force in the magnetic field. A little consideration will show that under these circumstances the path of the particle is changed from a straight line to a

circle described in a plane at right angles to the direction of the lines of force in the magnetic field

Let  $r$  be the radius of this circle. A particle of mass  $m$  moving round a circle with a velocity  $v$  exerts a centrifugal force tending to urge it away from the centre of the circle. The value of this is known to be

$$m v^2/r$$

Now for equilibrium the force tending to urge the particle away from the centre must equal the force due to the magnetic field tending to draw it in. Thus we have

$$\begin{aligned} H e v &= m \cdot v^2/r \\ \frac{m}{e} v &= H r \end{aligned} \quad (a)$$

Again the particle carries an electric charge. It can therefore be deflected by an electric field. Let  $X$  be the strength of the electric field. Then the force experienced by the particle is equal to  $X e$  and acts upon the particle in the direction of the lines of electric force. If now we arrange our apparatus so that the electric field and the magnetic field are at right angles to each other, the forces upon the particle due to the two fields will act along the same straight line, and by properly adjusting the sign of the electric field we can make the two forces oppose each other. It will then be possible to find a value for the electric field such that the two forces just neutralise each other and the particle goes on its path without deflection. When this is so we know that the mechanical forces on the particle due to electric and magnetic fields just balance each other. That is

$$\begin{aligned} H e v &= X e \\ v &= X/H \end{aligned} \quad (b)$$

Thus if we apply to the moving electrified particle

simultaneously an electric and magnetic field of such magnitudes that the particle pursues its path without any deviation, the ratio of the strengths of the two fields will give us directly the velocity of the particle. If, further, we can measure the radius of the circle into which the path of our particle is bent by the action of the magnetic field alone, we can, by equation (a), determine the value of the ratio  $m/e$ , or the mass to the charge for the particle we are investigating, since the value of  $v$  is now known from the previous experiment.

This ratio of the mass to the charge is one of the utmost importance in molecular physics. It may be noted that for ions in solutions it is the quantity of matter associated with the transference of unit quantity of electricity, that is to say, the electro-chemical equivalent. According to the latest values, the electro-chemical equivalent of hydrogen ions in solution is 0.000109 gm per coulomb. The values of the ratio for other ions can be deduced from this and a table of combining weights in the usual way, since every ion in solution carries by Faraday's laws either the same charge as the hydrogen ion or some simple multiple of it.

Owing to the way in which the volt and the ohm have been defined, the former as  $10^8$  and the latter as  $10^9$  absolute electro-magnetic units, the absolute unit of electro-magnetic charge is ten times the coulomb or practical unit of charge. The value of  $m/e$  for hydrogen in absolute units of charge is, therefore, 0.00109, or just a little greater than  $10^{-4}$  gms. per absolute electro-magnetic unit of charge.<sup>1</sup>

---

<sup>1</sup> The science of electricity is burdened with two distinct systems of units for the measurement of electrical magnitudes, the one founded on the consideration of the force with which two similar charges repel each other, the other on considerations of the induction of currents by magnets. The practical system of units is founded upon the latter, the volt being  $10^8$  and the ohm  $10^9$  absolute electro-magnetic units. The ampere and coulomb are thus 1/10th of the absolute

The principles just explained found their first application in the experiments of Professor Sir J. J. Thomson, on the cathode rays, experiments which may well be said to mark a new era in science. The experimental methods used by him have been

FIG 2—CATHODE RAY DEFLECTION TUBE

modified and improved upon in the light of subsequent discoveries, and the accuracy attained in the measurements greatly increased. In principle, however, the experiments remain the same, and on

---

units of currents and charge. To make confusion worse confounded, it has become usual in works and original papers on these subjects to give the value of  $m/e$  in electro-magnetic units, while the value of  $e$  itself is usually given in electrostatic units. Our statement that the force on the electron due to the magnetic field is equal to  $H e v$  implies that we are using the absolute electro-magnetic system of units, as this system has been defined in such a way as to make this statement true. As this system is the one more closely related to the units in actual use, we shall employ it throughout, except where the contrary is explicitly stated.

account of its historic interest the original apparatus used in these experiments will be described. Fig 2 is taken (by kind permission of Professor Sir J J Thomson) from a photograph of one of the tubes used by him for the experiment. The arrangement of the various parts will be seen more clearly from the diagrammatic representation in Fig 2A.

The cathode of the discharge tube is at C, and consists of an aluminium disc supported by a rod of the same metal and connected with the outside of the tube by a platinum wire sealed through the glass. The anode R is an aluminium rod placed in a side tube, while facing the cathode is a thick metal

FIG 2A—DIAGRAM OF CATHODE RAY TUBE

disc A, filling the tube but pierced with a small hole through which the cathode rays can pass in a narrow pencil. To define this beam of rays still further, a second metal disc B pierced with a still finer hole is placed some distance behind A. For convenience these two discs are mounted in a metal tube as shown in the figure. This tube and the anode R are connected to earth, while R and C are connected to the terminals of a large induction coil as shown in the photograph.

Thus, when the discharge is passed between C and R, a very fine well-marked pencil of cathode rays emerges from B. It is then made to pass between two parallel plates D and E of aluminium

which can be charged to any required difference of potential by connecting them to a large battery of small accumulators

This part of the tube is also placed between the poles of the little electro-magnet shown in the photograph, the lines of magnetic force being at right angles to the plane of the paper, and therefore at right angles to the electric field. Finally, the stream of cathode particles falls upon the walls of the bulb *Z*, which are covered with powdered zinc blende, its presence being marked by a spot of bright green phosphorescent light at the point of impact. The position of the spot in the original experiments was read off on a scale pasted on the outside of the tube.

To perform the experiment the magnetic field is first applied and the deflection of the spot of light measured. From this deflection and the dimensions of the different parts of the tube it is possible to calculate the radius of the circle into which the path of the rays has been bent by the magnetic field. The deflected and undeflected paths of the particles are indicated by the dotted lines in the diagram. The electric field is then applied and the difference of potential between the two plates gradually increased until the spot of light is brought back to its original position. The ratio of the electric to the magnetic field is then equal to the velocity of the cathode particles. The value of the ratio  $m/e$  can be calculated from this velocity and the known magnetic deflection as explained above.

The experiments were not without difficulty. It was at first found very difficult to obtain any deflection of the particles by means of an electric field. This was found to be due to the fact that the passage of the cathode rays through the residual gas in the discharge tube rendered it more or less conducting, so that the particles were moving

through what was practically a closed conductor, and were thus hardly affected by the external electric field. It was necessary in order to eliminate this effect to work with very high vacua.

On making the calculations it was found that the velocity of the particles depended principally upon the potential of the discharge, and to some extent also on the pressure of the residual gas in the tube and the nature of the electrodes and the gas in the tube. Even in the same tube the velocity of all the rays was not the same, so that on applying the magnetic field the single spot of light made by the cathode beam on the zinc blende screen was spread out into a little magnetic spectrum, as we may call it, each point of which corresponded to cathode rays moving with a definite velocity. In tubes at an exhaustion suitable for these experiments the velocities range, as a rule, from  $2 \times 10^9$  to  $3 \times 10^9$  cms per second, or about 1/10th of the velocity of light.

On evaluating the ratio  $m/e$  it was not found to suffer similar variations. The original experiments showed—and this has since been confirmed by many subsequent experiments—that, whatever the nature of the gas in the discharge tube, whatever the material of the cathode, whatever the working potential of the tube, the value of the ratio of the mass of the cathode particle to its charge is always the same. According to the latest determinations the value of this constant is  $5.65 \times 10^{-8}$  gms per unit of charge.

Again, although we have so far considered only the case of the cathode rays, they are not by any means the only source of these corpuscles, or electrons as they are now called. Similar electrons are given off in quantities from a clean metal surface when illuminated by ultra-violet light, or from the surface of the liquid sodium-potassium alloy under

the action of the light from an ordinary candle. Rontgen rays produce them whenever they fall upon any material object, and it is interesting to note that the velocity of the electrons thus produced is the same as that of the cathode rays in the Crookes tube

FIG 3.—MAGNETIC DEFLECTION OF THE CATHODE RAYS

from which the Rontgen rays proceed. Electrons are also emitted from incandescent metals at a high temperature, and in very large quantities when certain metallic oxides and notably those of barium and calcium are raised to a red heat. These elec-

trons have very little velocity of their own, but may very readily be given one by acting upon them with an electric field. If the heated oxide is raised to a potential  $P$  in absolute units, the work done on the electron by the field will be  $P \cdot e$ . If  $v$  is the velocity acquired by the electron, its kinetic energy is  $\frac{1}{2}mv^2$ . Hence, by the principle of the conservation of energy  $P \cdot e = \frac{1}{2}mv^2$  or  $v^2 = 2P \cdot e/m$ . Thus by suitably altering the potential of the hot oxide we can give to these electrons a suitable and known velocity.

Fig. 3 is a reproduction of an actual photograph of such a discharge. The cathode is a platinum strip carrying a minute speck of barium oxide, raised to a red heat by means of an electric current and charged to a potential of  $-240$  volts from a cabinet of small accumulators. The electrons given out by the heated  $\text{BaO}$  are projected by the field in a narrow pencil and are rendered visible by their action on the residual molecules of air in the exhausted tube. In the photograph a magnet has been placed behind the tube so that there is a magnetic field at right angles to the paths of the electrons, which are thus bent into the arc of a circle as shown in the figure. The fact that the circle is not completed is due to the gradual diffusion and absorption of the electrons by collision with the molecules of the gas in the tube.

The value of the ratio  $m/e$  for these elections has been measured by their discoverer Wehnelt and others. It may be noticed that as the potential  $P$  to which the cathode is raised is equal to  $\frac{1}{2}v^2 \cdot m/e$ , it is only necessary to measure the radius of the circle into which the rays are bent by a magnetic field of known strength  $H$  in order to be able to calculate both  $v$  and  $m/e$ . This fact has been applied by Lenard and others to measure the value of  $m/e$  for the electrons given off by metallic surfaces under the action of ultra-violet light.

# THE PHYSICS OF THE ELECTRON 21

TABLE I

Observer	Source of electrons	$e/m$ in a. u. per gm
Kaufmann	$\beta$ -rays (slow) from Radium	$1.77 \times 10^7$
Simon	Cathode rays	$1.73 \times 10^7$
Ewers	$\beta$ -rays from Polonium	$1.7 \times 10^7$
Classen	Cathode rays	$1.774 \times 10^7$
"	Hot lime	$1.776 \times 10^7$
Woltz	$\beta$ -rays (slow) from Radium	$1.767 \times 10^7$
Bestelmeyer	Hot lime	$1.766 \times 10^7$

The above table (Table I) gives a few of the more recent determinations of the ratio  $e/m$  for electrons from different sources. It will be seen that within very narrow limits indeed, especially considering the difficulties of the experiments, the ratio of the charge to the mass is the same for all electrons, whatever their origin and whatever their velocity, and differs very little from  $1.77 \times 10^7$ . The value of  $m/e$  or the electro-chemical equivalent of the electron, if we may so call it, is therefore  $5.65 \times 10^{-8}$ . For the hydrogen atom, as we have seen, the value is about  $10^{-4}$ . If we could assume that the charge  $e$  on an electron is the same as that on a monovalent ion in solution we see at once that the mass of the electron must be only about  $\frac{1}{1836}$  part of that of the hydrogen atom.

For this assumption, however, very little direct evidence could be adduced at the time it was made. It was one of those strokes of genius which have proved to be correct. To determine absolutely the mass of an electron we must find some method of determining the value of the electronic charge  $e$ . Fortunately this also has proved possible, owing to a discovery made in the Cavendish laboratory by Mr C. T. R. Wilson.

If a space saturated with water vapour is suddenly

chilled the surplus water over and above that which would saturate the space at the lower temperature in general separates out in little particles of water, forming within the space a thick mist or cloud. It was, however, shown many years ago by Aitken that this condensation always commenced round minute particles of dust, particles often far too small to be visible, yet sufficiently material to be caught by a well-packed tube of cotton wool. In the absence of these particles he found that a very considerable degree of supersaturation could be produced without any deposition of water and without any appearance of cloud or mist, and that it was only when the supersaturation became at least eightfold that a mist or cloud was produced. It appeared then that for a lesser degree of supersaturation than this the water vapour must have some nucleus about which to condense before a drop could be formed.

Gases under ordinary conditions are almost perfect insulators. Under the action of certain agents, such, for example, as Röntgen rays or any of the rays from radio-active substances, a gas becomes more or less conducting. It has been shown that this is due to the creation in the gas of systems, some negatively, some positively charged. In all probability these are produced by the ionising agent expelling a negative electron from the atom through which it passes, leaving the remainder of the molecule positively charged. The negative electron thus set free soon attracts to itself one or more atoms just as an uncharged pith ball is attracted by an electrified ebonite rod. The gas thus becomes filled with oppositely electrified systems consisting of clusters of three or four atoms together, which move under the action of an electric field in exactly the same way as the ions of an electrolyte move in the electrolysis of a solution. There is this difference, however, that, whereas the electrolytic ions are stable,

the gaseous ions, if left to themselves, gradually re-combine to form neutral molecules. Thus unless the supply is kept up by the continuous action of the ionising agent the conductivity will soon die away.

The mechanism of ionisation by the electrons emitted by a metal plate under the action of ultra-violet light is somewhat different. Here the electrons given off have not sufficient energy to expel an electron from the atoms of the surrounding gas and thus no positive ions are produced in the gas. The negative electrons, however, attract to themselves neutral molecules and form negative ions. It will be evident from the mode of formation that these ions bear the same charge as the electron which gave rise to them, that is to say, their ionic charge is the same as the electronic charge  $e$ . It may be pointed out in passing that since the ions are all of the same sign and produced at the same place, namely, the surface of the metal plate, a current can only be sent through the gas in one direction. If the metal plate is negative the ions will be repelled and thus carry a negative current from it to the positive electrode. If, however, the plate is positively charged the ions will be attracted back to it by the field and the gas will remain an insulator.

It occurred to C. T. R. Wilson that these ions might possibly serve as nuclei for the production of a fog or cloud in supersaturated air, and this was found on experiment to be the case. He was able to show that drops of water would condense on these negative ions when the supersaturation was only fourfold, while condensation occurred on positive ions also when the supersaturation was sixfold. It was found that when the supersaturation was increased to the proper extent each negative ion became the centre of a single drop of water, and if the conditions were fairly uniform these drops were all of the same size. It will be remembered that in

the case of the ions formed by ultra-violet light each of these drops will carry with it the electronic charge  $e$ , the magnitude of which we wish to determine

Every drop in a cloud is falling through the air under the action of gravity with a definite velocity. Clouds do not float in the air, though if the drops are sufficiently small they fall very slowly, owing to the great surface they present in comparison with their mass to the viscous drag of the air. Sir G. G. Stokes has shown that if  $r$  is the radius of a small drop of water and  $\eta$  the viscosity of the air, the velocity with which the drop will fall relative to the

air is  $\frac{2gr^2}{9\eta}$ , where  $g$  is, as usual, the acceleration due to gravity. The drops formed round the ions are all of the same size and fall at the same rate. We can thus measure the velocity  $v$  of their fall by watching the rate at which the surface of the cloud settles. This will enable us to calculate the radius  $r$  of the drop, and hence its mass  $M$ .

So far the cloud has been falling freely under the action of gravity. Let us apply a field of strength  $X$  in such a direction as to oppose the action of gravity, that is to say, with the positive plate above the cloud. The force on each drop due to the electric field is then  $Xe$ , while that due to gravity is  $Mg$ . We can adjust the field  $X$  until these two forces exactly balance each other, and the drop remains suspended in air like Mahomet's coffin. When this stage is reached we have

$$Xe = Mg$$

or

$$e = M \cdot g/X$$

But all these quantities are known, and thus the charge on the drop of water, which we have shown to be the same as that on the original electron, can be determined.

It remains to describe the apparatus devised for the experiment. It is shown in Fig 4. It is well

known that if a mass of gas is expanded in such a way that no heat is allowed to enter or leave it, the temperature will fall. The lowest temperature reached in any given expansion can be calculated

FIG 4—C T R WILSON'S EXPANSION APPARATUS

from the gas laws if the ratio of the specific heats of the gas is known. As gases are bad conductors of heat we can satisfy the conditions of the experiment by making the expansion sufficiently rapid. The mass of the gas is then cooled down to the calculated

temperature before any appreciable amount of heat has had time to enter the system

The method of making the expansion will be clear from the diagram. The tube H connects with a large vessel of some litres capacity kept exhausted by means of a water pump. It is closed by a rubber stopper C which can be suddenly withdrawn by means of the rod R, thus creating practically instantaneously a partial vacuum in this part of the apparatus. The air being thus suddenly withdrawn from beneath it, the light glass plunger P, which had been adjusted to a suitable height in the cylinder D, is forced down with great rapidity, thus producing within the experimental chamber L a very rapid expansion of an amount which depends only upon the initial position of the plunger P. The temperature in L is therefore suddenly lowered to a degree which can be calculated, and if the air in L was previously saturated, it will now be super-saturated to an extent which is measured by  $P/p$  where P and  $p$  are the vapour pressures of water at the initial and final temperatures.

In making an experiment the air in L is freed from all material nuclei by repeated expansions, the plunger is adjusted so as to make the super-saturation after expansion rather more than fourfold, the upper plate E, which is usually of zinc, is illuminated with ultra-violet light for a moment in order to produce a suitable supply of negative ions in the gas and the expansion is made. A cloud is formed on the negative ions and the rate at which the surface of it settles is taken. After it has fallen some little distance the upper plate E, which had been previously uncharged, is raised to a positive potential and its potential adjusted until the surface of the cloud is seen to remain stationary. If V is this potential and the lower plate at a distance  $d$  from the upper one is earthed, the strength of the electric

field is  $V/d$  and the electronic charge  $e$  is equal to  $Mgd/V$ , where  $M$  has been calculated by Stokes' law from the rate of fall of the cloud

The method was first applied in a rather different form by Professor Sir J J Thomson. In the form described, which is the one which has been used with the greatest success, it was performed by H A Wilson. We have, for the sake of making our argument logically complete, considered the case of the electrons produced by ultra-violet light, for in this case we have evidence that the charge we are measuring is really that carried by an electron. It has been shown, however, experimentally, that the value of the charge  $e$  is the same no matter how the ions are produced. Experiments carried out with ions produced by Rontgen rays or the various rays from radio-active materials gave exactly the same values for the charge  $e$ . Like the ratio  $m/e$ , the charge  $e$  is a universal constant. Some recent determinations of it are given in the following table

TABLE II

Observer	Carrier	$e$ (electrostatic units)
Begeman	Water drops (original method)	$4.67 \times 10^{-10}$
Roux	Sulphur drops	$4.17 \times 10^{-10}$
Ehrenhaft	Metallic dust	$4.65 \times 10^{-10}$
Millikan	Oil or mercury spray	$4.89 \times 10^{-10}$
Rutherford	Counting the $\alpha$ -rays	$4.65 \times 10^{-10}$
Planck	Theory of radiation	$4.69 \times 10^{-10}$

It will be seen from Table II that the values obtained for the electronic charge  $e$  by different observers working in different ways, though not so consistent as those obtained for the ratio  $e/m$ , yet

do not differ much from a mean value of about  $4.7 \times 10^{-10}$  electrostatic units, or  $1.57 \times 10^{-20}$  in the absolute electromagnetic unit of charge which is equal to 10 coulombs

The most extensive survey of the subject has been made by Millikan (see *Physical Review*, 1911). Instead of water drops he used very fine globules of oil or sometimes of mercury produced by an atomiser or fine spray. These drops could be passed as required into his apparatus, which very much resembled the chamber L in Fig 4, through a small hole made in the top plate. These globules did not evaporate appreciably, so that an individual drop could be isolated and kept under observation through a microscope for several hours consecutively. The microscope was fitted with an engraved glass scale in the eyepiece, on which the whole of the measurements on the motion of the drop could be made very accurately and conveniently. By properly adjusting the difference of potential between the upper and lower plates the drop could be kept in the field of view during the whole of the experiment. The measurements made and the calculation of the charge are precisely the same for the oil globule as for the water drop.

These drops were not originally charged, but picked up their charges from the surrounding air, which was ionised either by Röntgen rays or by radium. These comparatively large globules could collect and carry more than one electronic charge, seven or eight being a very usual number, though some drops had many more than this. The interchange of charges between the globule and the air could be easily observed with the microscope. The drop which had been poised almost motionless in the air for some time by the balanced action of gravity and the electric field would be seen to dart suddenly upwards, showing that the drop had captured another

charge and thus caused the electric force to increase, or perhaps on the other hand the drop would be seen to fall, having parted with one of its charges to some colliding molecule

The important point brought out by the experiment is that in every case it was found that the magnitude of the charge thus exchanged, which could be calculated by a simple application of the principles already explained, was exactly the electronic charge  $e$ , and the total charge on the globule at any time was always very exactly some integral multiple of this charge. An examination of the mass of figures collected by Professor Millikan leaves no room for doubting that the charge which we have denoted by  $e$  is a universal constant, and that every electrical charge is made up of an integral number of electrons, just as every fragment of an element is made up of a whole number of atoms.

From Table I we have the ratio  $e/m$ , equal to  $1.77 \times 10^7$ , for all electrons. Combining this result with the value just obtained for  $e$  we are driven to the conclusion that whatever the source from which they come all electrons have identically the same mass and charge, the former being  $8.8 \times 10^{-28}$  gms, the latter  $1.57 \times 10^{-19}$  coulombs. Such particles must form a constituent part of all matter.

The value of  $e$  ascribed to Professor Rutherford and also included in Table II was obtained from experiments of an entirely different nature made on the  $\alpha$ -particles. Before passing to these we must refer very briefly to an exceedingly beautiful extension of the method of drops which has recently been brought to perfection by the originator of the experiments.

In the experiments already described, the clouds obtained were fairly uniform, as the ionisation was intense and time was given for the ions formed to

diffuse through the body of the gas. Suppose, however, that we allow, say, a single  $\alpha$ -particle to cross our expansion chamber and at the same time make an expansion of the air in the chamber by the method

FIG. 5—THE TRACKS OF THE  $\alpha$ -PARTICLES

already described. The particle passes through the air, ionising it as it passes, and thus leaving behind it a trail of charged ions. Water drops at once form upon these from the now supersaturated air before they have had time either to diffuse into the rest of

the gas or to recombine. If the expansion chamber is suitably illuminated these drops appear as brilliant points of light all along the path traversed by the particle. In the case of the  $\alpha$ -particle the ions are so numerous that the track of the particle becomes visible as a continuous shining streak of light. In the case of an electron where the ionisation is less intense the appearance presented is that of a string of bright beads. We are thus able not merely to detect, but even to follow the path of a single particle of any kind providing it produces ionisation in a gas.

By the kindness of Mr C. T. R. Wilson, I am able to reproduce two of the photographs taken by him in this way. In Fig. 5 are shown the paths of a number of  $\alpha$ -particles. These have their origin in a small sample of radium placed just outside the chamber and shoot across the chamber as shown in the photograph until finally their energy, which is being spent in the work of separating the ionic charges along the whole of the path, finally becomes too small to produce ionisation, and the particles disappear from human ken.

FIG. 6—RONTGEN RAYS

Fig 6 is a photograph of the passage of a narrow beam of Rontgen rays through the expansion chamber, from A to A'. We have mentioned before that the Rontgen rays produce rapidly-moving cathode rays when they fall upon matter, in this remarkable photograph these cathode rays are made visible to us by the ions they produce. Here upon the dark background their tracks may be seen as a tangled skein of bright threads radiating out from the invisible track of the Rontgen rays. Each single thread represents the whole path of a single electron from its expulsion from the parent molecule under the action of the Rontgen rays, to the place where it finally becomes too weak to ionise. In some of the brighter threads the individual drops are clearly to be seen. The twists and turns in each little path are due to collisions between the cathode particle and the molecules of the surrounding air, or rather, perhaps, with the individual electrons contained in these molecules.

These photographs will perhaps do more than any argument, however cogent, to remove any doubt which may still be felt as to the objective reality of the electrons and other particles with which we have been dealing. Nothing but an actual particle could leave behind it such tracks as those shown in the photographs we have reproduced.

We have not space to deal with the many difficulties of the experiment or with the skill and ingenuity with which they have been overcome. Those interested may be referred to the original paper in the *Proceedings of the Royal Society* for 1912.

The method is still in its infancy, and the photographs so far obtained are hardly more than trial exposures. Already, however, several heated controversies have been settled, and many cherished hypotheses dethroned, as the result of the photographs obtained. To those of us who have been

working by indirect methods on some of the more obscure problems still left to us for solution, the method has come as a veritable giving of sight to the blind, and now that Mr C T R Wilson has perfected his apparatus and can turn his attention to using it as an instrument of research we may hope for many interesting and important results in the near future

## CHAPTER III

### THE POSITIVE PARTICLE

WE have already seen that positively charged particles are projected with high velocities from radium and other radioactive substances, and that they are also to be found in discharge tubes. Unlike the electron the positive particle has a mass comparable with that of an atom, no positive charge having yet been detected in association with any mass less than that of an hydrogen atom. The charge on a positive particle is, however, either the same as that on an electron or some simple multiple of it. The  $\alpha$ -rays, as the particles from radioactive substances are still called (a relic of the time when their nature was unknown) always carry a charge of  $2e$ . In discharge tubes, however, positive particles are found with all integral multiples up to  $8e$ . We shall see that we may regard the positive particles as atoms travelling with a high speed from which one or more electrons have been removed.

The positive particle can be deflected by electric and magnetic fields in the same way as the negative electron, and obeys the same laws. The deflection is in each case in the opposite direction to that of the electron, while, owing to the greater mass, the deflection is less than that for a similarly moving electron. The great ionising power of the positive particles makes the detection of the electrical deflection difficult. For these and other experimental reasons it is only recently that much light

has been thrown on their nature and properties. These difficulties have now been overcome, and the positive particle also is beginning to yield up its secrets. As the positive particle is always an atom of some kind, its investigation is, perhaps, from some points of view, of even greater interest than that of the electron.

The greater energy of these particles is, however, in some ways an advantage. It enables us to deal with individual particles, whereas in the case of the electron we can only deal with large numbers. Thus our measurements gain, perhaps, in definiteness although they may lose somewhat in numerical precision.

If  $e$  be the charge on a single  $\alpha$ -particle, the total charge carried by  $N$  particles is  $N e$ , and if  $N$  is sufficiently large this charge will be large enough to be directly measured by an electroscope or electrometer. If we can further determine the number of the particles which conveyed this charge we shall have made a direct determination of the charge  $e$ .

The experiments are best performed using the  $\alpha$ -particles from radium, polonium, or some other radioactive substance. They were carried out almost simultaneously by Rutherford and by Regener. In Rutherford's experiments the  $\alpha$ -particle was detected by the ionisation it produced in a special chamber, the entry of each  $\alpha$ -particle into the apparatus being notified by a kick of the needle of a sensitive electrometer. In Regener's experiments the number of scintillations produced by the particles in a given time on a fluorescent screen was counted. The former method was the more satisfactory from a theoretical view, as there was at the time no direct evidence that every particle produced a scintillation when it struck a screen, although this has since been shown to be the case by Rutherford. It was also proved by the fact that the two experimenters

reached almost the same value for the charge on the  $\alpha$ -particle. The experiment of Regener is simpler to carry out than the electrical method of Rutherford, and granting his assumptions, is probably capable of greater accuracy.

Regener's apparatus is shown in Fig 7. Fig 7a shows the "counting" apparatus, Fig 7b the

FIG 7—REGENER'S APPARATUS

apparatus for measuring the total charge carried by the rays.

The counting apparatus is very simple. It consists of a long tube closed at one end by a brass plate *c, c*, bored with a circular hole some centimetre in diameter. Across this is sealed a thin glass cover-slip bearing on its under surface the fluorescent screen *D*, in this case a thin plate cut from a crystal of brown diamond, a substance chosen by Regener after many trials as the most suitable for the

purpose. Rutherford has since used prepared screens of powdered willemite with equal success

A high power microscope was focussed on the diamond plate for viewing the scintillations, which, numbering about one every two seconds, were easily counted. The source of the  $\alpha$ -particles in Regener's experiments was a plate of polonium, placed at P, some 12.7 cms from the diamond screen. The whole tube was carefully exhausted, so that there should be no absorption of the particles before reaching the screen.

The number of scintillations in a given time was counted, and the area  $A$  of the aperture in the brass plate and its distance  $R$  from the polonium carefully determined. If  $n$  is the number of particles hitting the screen in a time  $t$  seconds, then the number of particles emitted by the polonium per second across a hemisphere drawn about its upper surface is

$$N = \frac{2\pi R^2}{A} \frac{n}{t},$$

assuming that the particles are given out equally in all directions. This assumption was verified by Rutherford in a separate experiment. For the disc used by Regener  $N$  was found to be  $3.935 \times 10^6$ .

To measure the total charge carried by the  $\alpha$ -particles from the disc a Faraday cylinder was used\*. This consisted of a partially closed brass cylinder F (Fig. 7b) enclosed in a glass chamber exhausted to a very high vacuum to avoid any loss of charge by ionisation in residual air. The polonium was mounted at P, so that the  $\alpha$ -particles from its upper surface entered the cylinder. Here they gave up their charges to it, gradually raising it to a positive potential, which could be measured by an electrometer or electroSCOPE connected to the metal electrode E.

\* This method of measuring small currents by the electrometer is one in everyday use in this class of

experimental work and deserves a little further consideration. Let  $C$  be the electrical capacity of the Faraday cylinder and its connections, and suppose the cylinder is placed at zero potential by connecting it to earth. Insulate and note the reading after some suitable interval of time, say  $t$  seconds. Let  $V$  be the potential corresponding to this reading, this can easily be determined by calibrating the instrument with suitable known potentials. The charge given to the electrode in the time  $t$  is then  $CV$ , so that the current between  $P$  and  $F$  is  $CV/t$ .

Since the capacity of the system can be made very small the method is far more sensitive than the most delicate galvanometer. The capacity of an electroscope of the C. I. R. Wilson type with its electrode and all its connections need not be greater than 4 or 5 cms., or, say,  $5 \times 10^{-12}$  farads. The electroscope will easily give a deflection of 100 divisions for a potential of 1 volt, while a movement of the gold leaf of a division per minute can be detected with certainty. This corresponds to a current of  $10^{-11}$  amperes. The best galvanometers give a perceptible deflection for a current of about  $10^{-11}$  amperes. The electroscope method is, therefore, about ten thousand times as sensitive as the most delicate galvanometer.

In the present case the value of  $CV/t$  gives the charge carried by the  $\alpha$ -particles per second from the upper surface of the polonium disc. In electrostatic units it was found to be 0.00377. This was the charge carried by the  $3.935 \times 10^5$   $\alpha$ -particles emitted by the polonium. The charge on each particle was therefore  $0.00377/3.935 \times 10^5$  or  $9.58 \times 10^{-10}$  in electrostatic units. Rutherford's value was  $9.30 \times 10^{-10}$  in the same units.

It will be seen that these numbers are almost exactly twice the value  $4.7 \times 10^{-10}$  e.s.u., which represents the mean value for the electronic charge  $e$ .

In fact the value of  $2\epsilon$  is almost midway between these experimental numbers. The charge on the  $\alpha$ -particle is therefore exactly twice the charge on the electron. The  $\alpha$ -particle is therefore an atom which has lost two electrons. This is characteristic of all the  $\alpha$ -particles emitted by radioactive substances which appear to differ from each other only in velocity.

We have stated that the  $\alpha$ -particle is an atom, the question arises of what element is it an atom? The ratio of the mass to the charge can be determined for the  $\alpha$ -particle in the same way as for the electron, neglecting the different experimental arrangements required. No great accuracy has, however, been reached, as the deflection of these particles from radioactive substances even in the strongest magnetic fields is small. According to Rutherford, the ratio of mass to charge for the  $\alpha$ -particle from radium is  $1.97 \times 10^{-4}$ , and we have seen that they carry two charges, or, in the language of electrolysis, are divalent. The electro-chemical equivalent of hydrogen is  $10^{-4}$ , so that if we can assume that the ion in solution carries the electronic charge  $\epsilon$ , the atomic weight of the  $\alpha$ -particles would be 3.84, which is very near 3.96, the atomic weight of helium. Conversely, if we can show that the  $\alpha$ -particle is an atom of helium we shall have direct evidence that our assumption that the monovalent ion carries the same charge as an electron is correct.

The proof of the nature of the  $\alpha$ -particle has been given by Rutherford, to whom we owe so much of our knowledge of these rays. The experiment is based on the fact that the  $\alpha$ -rays, owing to the great speed with which they are projected by the parent molecule, are able to pass through thin sheets of solid substances which are perfectly impervious to the molecules of ordinary gases.

The substance used as the source of  $\alpha$ -particles

was radium emanation, the radioactive gas which is the first decomposition product of radium, and on which Professor Ramsay proposed to bestow the name of niton. This gas, which is disengaged from solutions of radium in water, after being purified in various ways, is finally passed into a fine thin-walled glass tube, the end of which has been carefully sealed. This is enclosed by a wider thick-walled glass tube which is also made quite air-tight and has in its upper portion two electrodes. The spectrum of the discharge between these two electrodes enables us to determine the nature of the gases in this outer tube. There is no connection between the inner and outer tubes, so that nothing can pass from the one to the other, except the  $\alpha$ -rays. This point was tested by filling the inner tube with helium and allowing the apparatus to stand for some days. No trace of the helium spectrum was obtained in the outer tube under these circumstances. When, however, the inner tube was filled with emanation, the  $\alpha$ -particles emitted were able to pass through the thin glass walls, and, being stopped by the thicker tube beyond, collected in the space between the two tubes.

Slowly, as the experiment went on, the spectrum of helium began to appear, becoming brighter and more complete as more and more of the rays passed through the inner tube, until at the end of a few hours the complete helium spectrum was obtained. The blank experiments were far more in number and severity than has been described here. They left no doubt that the  $\alpha$ -particles were indeed atoms of helium, differing from the ordinary atoms of the gas only in their velocity and charge. We have seen above that this result leads directly to the conclusion that the charge on a monovalent ion in a solution is the atom of electricity which we denote by  $e$ .

This is one of the most direct proofs of this very

important fact. There are, however, many others of very diverse natures, some of which we shall have occasion to discuss when dealing with the phenomena on which they are founded.

The charge carried by a monovalent ion in solution and the electronic charge are thus the same, the value for the latter is, as we have seen, very near  $4.7 \times 10^{-10}$  esu, or  $1.57 \times 10^{-20}$  in our electromagnetic units. The ratio of the mass to the charge for the hydrogen atom in solution is, as we have seen,  $1.04 \times 10^{-4}$ . Thus the mass of the hydrogen atom is  $1.04 \times 10^{-4} e$ , or  $1.63 \times 10^{-21}$  gms. This is therefore the value in grammes of the chemical unit of atomic weight, and we can at once calculate from it the actual mass of any atom of which the chemical atomic weight is known. The accuracy of the result depends only on the accuracy with which the value of  $e$  can be determined. A reference to Table II (page 27) will show that the error in the value we have used probably does not exceed 2% or 3% at most.

Since the mass of a cubic centimetre of hydrogen at normal temperature and pressure is almost exactly  $9 \times 10^{-6}$  gms, the number of hydrogen atoms contained in 1 cub. cm of a gas under these conditions is  $9 \times 10^{-6} / 1.63 \times 10^{-21}$ , or  $5.5 \times 10^{15}$ . The number of molecules in 1 c.c. of hydrogen gas is therefore  $2.75 \times 10^{15}$ . By Avogadro's hypothesis this number is independent of the nature of the gas.

## CHAPTER IV

### THE NEW METHOD OF ANALYSIS

WE have considered so far the case of the positively charged particles from radioactive substances, and have seen how their mass, charge and chemical nature have been determined, and how these determinations have given us the most certain and accurate estimate of the actual mass of a hydrogen atom. The information obtainable was, however, limited by the fact that these particles are all of one kind, consisting always of atoms of helium.

We have already mentioned that it is possible, in a discharge tube, to endow atoms and molecules of ordinary matter with those properties of high velocity and electric charge which have made the  $\alpha$ -particles so amenable to experiment. The process may be regarded as follows. When the two electrodes of the discharge tube are connected to the poles of an induction coil, the molecules of the rarefied gas in the tube are subjected to a very strong electric tension. This tension, acting upon the negative electrons, which, as we have seen, are contained in all molecules, causes one or more of them to be displaced from the molecule, leaving the remainder positively charged. This positive particle, as we may now call it, is driven with great velocity towards the cathode by the action of the electric field which produced it.

If the cathode is suitably perforated, the positive particle will pass through it, and emerge on the

further side with this velocity unimpaired. It can then be detected by allowing it to fall either on a fluorescent screen, or preferably on a photographic plate, where it will produce a permanent record, which can be measured at leisure with suitable instruments of precision.

The experiments, for reasons to which we have already alluded, presented many difficulties. It is

FIG 8—THOMSON'S POSITIVE RAY APPARATUS

only after several years of experiment that Professor Sir J. J. Thomson has at last perfected an apparatus which allows him to measure these particles with accuracy and certainty.

A general idea of the apparatus can be obtained from Fig 8, which is reproduced from a photograph of one of Professor Thomson's tubes. The details

are shown more clearly in the accompanying diagram, Fig 9, which represents a section of part of the apparatus as seen from above

The apparatus consists of two parts the discharge tube proper, where the particles are produced, and the "camera," where their presence is detected and their masses determined. The discharge tube proper consists of a large bulb T, some 30 cms in diameter. The anode A (Fig 8) is placed in a side tube, while the cathode C (Fig 9) occupies the neck

FIG 9—THOMSON'S POSITIVE RAY TUBE

of the bulb. The gas to be experimented on enters the bulb through the tubes at *e*, and is removed through the tube *g* by a Gæde pump, which is worked sufficiently rapidly to keep the gas in T at a suitably low pressure.

The cathode C (Fig. 9) is an aluminium rod pierced with a very fine copper tube about 8 cms long and less than 1-roth mm in diameter. An exceedingly fine pencil of positive rays is thus obtained. It is evident that with a tube so narrow any stray magnetic field will cause the particles to

hit the walls of the tube and be lost. To prevent this the copper tube is enclosed for the greater part of its length in a thick iron tube S, shaded in the diagram, while thick iron screens I, I, protect the main discharge from the influence of the magnet.

Owing to the intensity of the discharge the cathode becomes very hot, and it is necessary, in order to protect the numerous sealing-wax joints, to surround them with a water cooling jacket, as shown in Fig. 8.

On leaving the copper tube, the rays pass between M and N, two soft iron blocks let in through the sides of the tube (which is here made of ebonite) and carefully waxed round, so as to be completely vacuum tight. These blocks serve two purposes. In the first place they form the pole pieces of the electro-magnet E, E, from which, however, they are electrically insulated by two thin strips of mica *m, m*. This insulation enables them to be charged positively and negatively respectively, by means of a cabinet of small storage cells, and thus to serve as electrodes for the application of an electrostatic field.

In this way the positive particles can be subjected at the same time to a magnetic and an electric field. It will be noticed that, whereas in the case of the cathode ray experiments described in an earlier chapter the two fields were at right angles to each other, in this case the two fields are parallel, and the corresponding deflections therefore at right angles to each other.

After passing through these fields, the rays fall either upon the glass plate Z, which is covered with powdered willemite, or upon a photographic plate, which can be introduced when required immediately in front of Z by suitable devices.

The side tube L leads to a tube filled with charcoal and immersed during the experiment in liquid air, a device due originally to Sir James Dewar for

absorbing as completely as possible the gases in this part of the apparatus. This detail, apparently insignificant in itself, has had much to do with the success of the method. If the gas in the camera is at the pressure most suitable for the production of positive rays in the discharge tube, the effects observed on the screen are found to be almost entirely secondary. The residual gas in the camera becomes strongly ionised by the action of the positive rays upon it. The latter are thus travelling through an atmosphere charged with negative electrons, with which they readily combine to form neutral molecules again. When this has taken place, the particle is no longer acted upon by electric or magnetic fields. The exact extent of its deflection will depend upon the length of time during which it succeeded in retaining its charge. These secondary effects still make their appearance upon some of the photographs taken. They can, however, always be detected by the fact that they either disappear or alter in position or appearance if the pressure in the camera is slightly lowered or slightly raised.

The charcoal and liquid air method enables us to remove the residual gas so rapidly that it is possible to have the pressure in the camera considerably lower than that in the discharge tube, the diffusion along the long narrow copper tube, which is their only connection, being comparatively slow. In this way the production and the measurements of the particles can both be carried on under the most favourable conditions.

Let us consider the course of the positive particle from its genesis in the discharge tube to its stoppage on the photographic plate. Particles formed near the anode will fall through practically the whole of the difference of potential between the electrodes of the discharge tube, some 30,000 or 40,000 volts. The energy they acquire will thus be  $V \times E$ , where  $V$

is this difference of potential, and  $E$  the charge on the particle. Their velocity  $v$ , on reaching the cathode, will thus be given by

$$v^2 = 2 VE/m$$

FIG 10—POSITIVE RAY PARABOLAS

This is the maximum velocity the particles can attain. Those commencing their existence nearer the cathode than this only fall through a fraction of the full potential  $V$ , and thus acquire only a fraction

of this maximum velocity. Thus, the stream of rays passing through the cathode will contain particles moving with all velocities up to a certain maximum.

On passing into the electric and magnetic fields at MN they will be acted upon by forces equal to  $XE$  and  $HEv$  respectively, where  $X$  is the electric and  $H$  the magnetic field, exactly as in the case of the cathode particles, the only difference being that the directions of the deflections will be in the opposite directions to those of the negative particles. It can be shown\* that these forces will cause the point at which the particle strikes  $Z$  to be deflected through

distances equal to  $k_1 \frac{HE}{mv}$  in the case of the magnetic field, and  $k_2 \frac{XE}{mv^2}$  in the case of the electric field,  $k_1$  and  $k_2$  being constants which depend only on the relative dimensions of the various parts of the apparatus. It must be remembered that the fields have been so disposed that these two deflections will take place at right angles to each other.

Thus if  $O$  (Fig. 10) represents the position on the plate of the undeflected rays, and  $OX$ ,  $OY$  are the directions of the electric and magnetic deflections, the particle, after passing through the two fields, will be deflected to some point  $P$  such that

$$PK = x = k_2 \frac{XE}{mv^2} \quad (\text{electric deflection}) \quad (a)$$

$$PJ = y = k_1 \frac{HE}{mv} \quad (\text{magnetic deflection}) \quad (b)$$

We see from these equations that

$$y/x = \left( \frac{k_1 H}{k_2 X} \right) v \quad (c)$$

$$y^2/x = \left( \frac{k_1^2 H^2}{k_2 X} \right) \frac{E}{m} \quad (d)$$

If the strengths of the two fields are kept the same throughout the experiment, all the quantities within the brackets will be constant. Thus,  $y/\tau$  will be a measure of the velocity of the deflected particle, while the ratio  $y^2/\tau$  will measure the ratio of the charge to the mass.

If all the particles were identical, and had the same velocity, the spot O would simply be shifted to the point P. As we have seen, the velocities of the particles vary considerably. The rays will therefore not be deflected to a single spot, even if their mass and charge are identical, but will be drawn out into a line or band. By equation (d) all the particles for which  $E/m$  is the same will, however, lie on some curve for which the value of  $y^2/\tau$  is constant, such a curve is known as a parabola.

If the particles emerging from the cathode consist of atoms of differing atomic weight, they will be sorted out into a series of parabolas one above the other, each curve corresponding to some definite value of  $E/m$ . Since the velocity which is proportional to  $y/x$  cannot exceed a certain value, these curves will not be complete, but will stop short at some definite distance from the axis OY. The appearance of the plate after exposure should therefore be somewhat as shown in the top left-hand quadrant Fig 10, where two such parabolas are shown.

To measure the curves, drop any perpendicular on OX, cutting the curves in  $l$  and  $m$ , and the axis in  $n$ . Then, from equation (a) it can be seen that

$$ln^2/mn^2 = y_1^2/y_2^2 = \left(\frac{E_2}{m_2}\right) - \left(\frac{E_1}{m_1}\right)$$

since the value of  $x$  is the same for all points along the line  $lmm$ . Thus, if  $E_1 = E_2$ , that is to say, if the two particles carry the same charge, the ratio of the masses of the two sets of particles is inversely proportional to the square of their distance from OX.

The line OX has no real existence on the plate, but the apparatus can be arranged so that the direction of the deflections are parallel to the edges of the photographic plate, while the position of O is always marked by a very bright spot caused by rays

FIG. 11.—PARABOLAS DUE TO MULTIPLE-CHARGED MERCURY ATOMS

which come through the cathode uncharged, and are therefore undeflected. A more accurate method is to reverse the field halfway through the exposure. The direction of the deflection is thus reversed, and symmetrical parabolas are formed on the opposite side of OX as shown in Fig. 10. The distance

between the two branches of the same curve is then twice the distance of either from the line OX

It will have been noted that the ratio of the squares on these ordinates does not give directly the ratio of the masses of the particles, but only the

FIG 12—TYPICAL POSITIVE RAY PHOTOGRAPH ATMOSPHERIC NITROGEN

ratio of what we may term their electro-chemical equivalents. Fortunately, however, the majority of the particles carry the single electronic charge  $e$ , while in any case the charge  $E$  on the positive particle cannot be more than a small integral multiple of

this Very little uncertainty is as a rule introduced from this cause, though it does occasionally arise Mercury is the greatest offender in this respect, as mercury atoms carrying as many as eight charges are sometimes to be detected Thus, five of the

six parabolas on Fig 11, which is reproduced from one of Prof Thomson's photographs, are due to atoms of mercury, carrying respectively one, two, three, four, and eight charges The latter line, though clear on the negative, is too faint to show up clearly in the reproduction

The measurement and interpretation of the results can best be illustrated by an actual example. Fig. 12 represents a fairly typical photograph obtained with the apparatus. The gas in the discharge tube in this case was atmospheric nitrogen, that is to say, air from which the oxygen had been extracted. Table III contains the actual measurements made on this plate.

The first column gives the distance of the different parabolas from the axis OX, measured along some common ordinate as explained above. The second column gives the value deduced from these figures for the relative masses of the particles, assuming that they all carry the same charge. If the charge carried is double or treble this value, the corresponding mass so obtained will be half, one-third and so on, of the actual mass of the particle. The standard line on this plate was the innermost one of all, which, as its appearance shows, is due to mercury carrying a single charge. The mass of this particle is for convenience taken as being equal to its atomic weight (200).

Examining the table, it will be seen that the three inner parabolas represent particles having a value of  $m/E$  of 200,  $\frac{1}{2}$  (200), and  $\frac{1}{3}$  (200). They are due to mercury atoms having, respectively, one, two, and three charges. Mercury vapour is always present in the tube unless special precautions are taken to exclude it, as it is used in the vacuum pumps attached to the apparatus. The next line is made by particles having a mass of 44, these are singly charged molecules of carbon dioxide, carbon compounds being usually present as impurities in small quantities.

The argon line (39) is the long bright parabola, immediately below the very thick bright line (28), due to molecules of nitrogen with a single positive charge. This, as might be expected, is the brightest

line in the photograph. The parabola for which  $d$  is 23.1 is very faint on the reproduction. It probably represents Neon (20), though there is also

FIG 13—POSITIVE RAY PARABOLAS

the possibility that it is formed by argon atoms with a double charge, as the argon line (40) is very bright. Our method does not enable us to distinguish between these alternatives.

The triplet of lines which follow is due to atoms of oxygen, nitrogen, and carbon. The last line on

the plate indicating a value 7 is the nitrogen atom with a double charge. The hydrogen line, which is nearly always present, has been deflected entirely off the plate by the large magnetic field applied in order to separate the heavier constituents.

It will thus be seen that all the lines on our plate correspond to elements which we might expect to find present from the nature of the gas employed. There are no lines unexplained, and the values obtained for the relative masses of the particles correspond very closely to the atomic and molecular weights determined from chemical considerations.

The faint lines seen on Fig. 12 joining some of the parabolas to the origin are due to the secondary effects which we have already mentioned. The mercury parabolas, however, as will be seen from the figure, do actually extend to within a very short distance of the origin. This is due to quite a different cause. Turning back to equation (a), it will be seen that the electric deflection is proportional to the charge  $E_1$  carried by the particle in the electric field divided by  $\frac{1}{2}mv^2$ , the kinetic energy of the particle. We have seen that the maximum value of the latter is equal to  $V - E_2$ , where  $V$  is the potential of the discharge, and  $E_2$  the charge carried by the particle in the discharge tube. The minimum value of the electric deflection, that is to say, the nearest point to which the parabolas can extend, will be proportional to  $E_1/E_2$ , and will thus be the same for all particles, whatever their mass and charge, if each particle carries the same charge in the tube as in the camera. Thus all the curves will stop short at a certain line drawn parallel to OY. This is well shown in Figs. 13 and 14.

If, however, a particle in the discharge tube having a double or treble charge loses one or more of these extra charges before the electric field at MN is reached, the value of  $E_2/E_1$  will be greater than

unity, and the parabola will extend further, towards the axis OY

These extensions of the parabolas are very clearly shown in the three inner curves of Fig 13, where an almost complete break occurs between the termination of the original parabola and its continuation by particles which have parted with one of their original charges. These three parabolas are due respectively

FIG 14.—GAS EVOLVED FROM PLATINUM

to Mercury (200), Xenon (132), and Krypton (83). The two outer curves, representing Argon (40) and the nitrogen molecule (28), end abruptly at the normal distance from OY.

The best example of the effect is, however, shown by the mercury lines in Fig 11. The normal mercury atom in the discharge tube apparently carries a charge of  $8e$ , and approaches the cathode with an amount of energy equivalent to this. The innermost mercury parabola (Fig 11) gives a value for the mass just 200 times that of the hydrogen atom.

It is therefore due to a mercury atom carrying a unit charge, and having thus only one-eighth of the charge it carried in the discharge tube. The value of  $E_1/E_2$  is thus  $\frac{1}{8}$ , and the parabola extends to one-eighth of the usual minimum distance from the vertical axis. The next line ( $m = 100$ ) is due to atoms with two charges, and extends to one-quarter of the usual minimum distance, and so on, until the last parabola, which corresponds to a mercury atom with eight charges (the same number as in the discharge), ends up at the usual distance from the axis.

This gradual shortening of the parabolas of the differently charged mercury atoms is beautifully shown in Fig 11, where the terminations of the five mercury parabolas can be seen to lie exactly on a straight line through the point O inclined at an angle to OY, as would be expected on the above theory.

It will be noticed that the lines decrease in intensity as the number of charges carried is increased. This is always to be observed on the photographs, and is a fact which sometimes helps us to the right interpretation of a doubtful line in a photograph. For example, if the line indicating a mass of 20 on Fig 12 had been brighter than the Argon line (40) we should have been able to say definitely that it was due to atoms of Neon, and not to Argon atoms with a double charge.

The plates so far described were all taken using large magnetic fields in order to obtain a suitable dispersion of the heavier atoms. The last plate of the series (Fig 14) was taken with a smaller magnetic dispersion, and shows the lines due to some of the lighter elements. It is of peculiar interest at the present moment, as it is one of the photographs which shows the mysterious line due to particles for which the ratio of the mass to the charge is exactly three times that for the singly charged hydrogen atom. On this account it may perhaps be of

interest to give the actual measurements made on this plate (Table IV) The first column of the table gives the actual measurements of a common ordinate of the different parabolas, the second column the corresponding values of  $m/E$ , the ratio for the hydrogen atom being taken as unity

The gas used in the experiment was a sample of that mysterious gas which is evolved in considerable quantities when any metal is heated, or better still, as in the present case, bombarded with cathode rays in a vacuum tube That gases were evolved under these circumstances had been known for some considerable time, but their analysis had not been

TABLE IV

Gases evolved from Platinum bombarded with Cathode rays for 6 hours (See Fig 14)

$d$ mm	$m/E$	Probable cause of line
27.0	1.00	H + Hydrogen atom
19.1	2.0	H <sub>2</sub> + Hydrogen molecule
15.6	3.0	} Unknown element
7.8	12	C + Carbon atom
6.7	16	O + Oxygen atom
5.8	21	Ne + Neon atom (20)
4.8	32	O <sub>2</sub> + Oxygen molecule

previously effected As will be seen from the table, the gas consists principally of hydrogen, but helium and neon are also present, while the plate also shows traces of carbon and oxygen, probably due to impurities in the apparatus

In addition to these known substances there is also very clearly marked a line, the third from the top of the plate, which cannot be assigned to any known element or compound There was at first the possibility that it might be due to a carbon atom

carrying four elementary charges, but this hypothesis was found to be untenable. In the first place the line under consideration is much brighter than that due to the singly charged carbon atoms, while we have seen that on a given plate the curves due to multiply charged atoms are invariably fainter than those due to atoms of the same substance having a single charge. In the second place, when precautions were taken to exclude carbon compounds from the apparatus the carbon line (12) completely disappeared, while the line 3 remained as bright as ever.

Only two possibilities remain. The line may be due to a previously unknown element of atomic weight 3, or it is due to a hitherto unknown modification of hydrogen  $H_3$  corresponding to ozone. If the latter is the case, the substance has some quite unexpected properties, as it is certainly not destroyed by sparking with excess of oxygen. Professor Sir J. J. Thomson is still actively pursuing his experiments on this substance, and some very interesting results may be expected. Until these experiments are completed it would be premature to venture any further opinion as to the real nature of this new gas.

Another parabola which is found when the gases from liquid air residues are introduced into the tube suggests interesting possibilities. This is a line giving a value for  $m/E$  equal to 22. This might possibly be a molecule of carbon dioxide ( $44$ ) with a double charge, but from the fact that it appears only in these mixtures of the rarer atmospheric gases, and that it is quite well marked even when the  $CO_2$  and  $CO$  lines are absent, seems to point to it being a new compound  $NeH_2$  of neon and hydrogen.

A few further points of interest in the photographs may be noted. The bright central spot shown in all the figures is due to the particles which have lost their charge during their passage through

the long copper canal tube, and are therefore undeflected by any combination of electric and magnetic fields. The atoms of some elements have, such a strong attraction for the surrounding negative electrons that they actually take up more of them than would be sufficient to neutralise the original positive charge. They thus enter the deflecting fields with a negative instead of a positive charge, and so give rise to parabolas in the opposite quadrant to those due to the positive particles, but giving, of course, the same values for  $m/E$ . Oxygen and the halogens if present in any quantity almost invariably give these negative curves. Strangely enough hydrogen, which is generally reckoned among the more electro-positive elements, also frequently shows the same effect. It has never been found with nitrogen or helium.

We have so far only been considering the relative values on the ratio  $m/E$  for the different particles. By measuring the dimensions of the different parts of the apparatus and calculating the actual values of the constants  $k_1$  and  $k_2$ , the absolute value of this ratio for any given parabola can be deduced. Such a determination was made by Professor Sir J. J. Thomson, and it was found that the absolute value for the outermost parabola of all was almost exactly  $10^{-4}$ . We have seen that this is the value of the ratio for a hydrogen ion in solution or a hydrogen atom carrying a single charge. The particles with which we have been dealing are therefore actual atoms and molecules of the substances in the discharge tube, as we have tacitly assumed in the foregoing pages.

We have now described in some detail the principal features of the new method of molecular analysis. Its importance can hardly be exaggerated. In the first place it enables us to detect with certainty the presence in a gaseous mixture of far smaller

quantities of an element than could be accomplished by any other method known to science. Professor Thomson has given the following striking illustration of the delicacy of the method. It was found that the photographs taken with atmospheric argon in the apparatus always showed the helium line faint but quite distinct. In this particular experiment the volume of the discharge tube was about 2 litres, and the pressure of the gas in the tube  $1/300$  mm of mercury. The gas experimented on would therefore have had a volume of about  $1/100$  c.c. at atmospheric pressure. This is approximately the quantity of argon in 1 c.c. of air at atmospheric pressure. We are thus able to detect the helium present in a single cubic centimetre of air. According to the determinations of Professor Ramsay this amounts to no more than four millionths of a cubic centimetre.

The new method has the further advantage over spectroscopic analysis that it gives directly the atomic or molecular weight of the substance under experiment. Thus the photograph of Fig. 14 not only reveals the existence of a new gas but gives at once its molecular weight.

Lastly—and this is perhaps most important of all from the point of view of an intimate study of the modes and methods of chemical combination and decomposition—the time taken for each single particle to register its presence and mass is exceedingly minute. A very moderate value for the speed of the positive particles is  $10^8$  cms. per second (about 620 miles per second). Their path in the discharge tube is not more than 50 cms. in all. Thus a particle when caught by the discharge will register itself on the photographic plate in considerably less than one millionth of a second.

We might therefore reasonably expect to find on the photographs curves corresponding to temporary combinations of atoms so unstable that their whole

period of existence is not greater than one millionth of a second, if any such combinations are formed in the discharge tube. Thus in the case of chemical reactions taking place within the discharge tube we might expect to find on the plate traces not merely of the stable products of the reaction but also of any intermediate stages occurring in the course of the reaction. The field thus opened up for an intimate study of the mechanism of chemical reactions is illimitable.

Though little has as yet been accomplished along these lines, the experiments already made show that this expectation is not unfounded. As a very simple illustration of the application of the method we may take the case of phosgene,  $\text{COCl}_2$ . When this was introduced into the apparatus the photographs showed that, in addition to the molecules of undecomposed phosgene (99), the carriers of positive electricity were molecules of carbon monoxide (28) and atoms of chlorine (35.5). The lines due to single atoms of carbon and oxygen were very faint indeed, thus showing that the decomposition of the compound by the discharge consisted of the separation of the chlorine atoms from the CO molecule, the bond between the carbon and oxygen atoms remaining intact.

This is a simple case where the results obtained might easily have been predicted. Another interesting case is that of methane,  $\text{CH}_4$ . When this gas is subjected to the discharge a group of five lines appears on the photographic plate, indicating the presence of particles having masses 12, 13, 14, 15 and 16 times that of the hydrogen atom. These correspond to particles having the composition C, CH,  $\text{CH}_2$ ,  $\text{CH}_3$ , and  $\text{CH}_4$  respectively.

We have been dealing so far with the many advantages of the method. Some of its limitations should perhaps be pointed out. In the first place

the substance to be experimented on must be either gaseous or capable of exerting a vapour pressure at ordinary temperatures. A more important defect, and one which is shared by the spectroscopic method, is that an element may be present in considerable quantity in the discharge tube without producing a corresponding trace upon the photographic plate. Thus, although many metals have compounds sufficiently volatile for the purpose of the experiment, mercury and nickel are the only metallic elements which have so far been detected by the method.

FIG 15—APPARATUS FOR THE ELECTRICAL MEASUREMENT OF THE POSITIVE RAYS

One word may be added as to the relative intensity of the different lines on a given photograph. It is found that in general this is far from representing the actual proportion of the particles in the stream having masses corresponding to the different lines. For some reason at present unexplained, a given number of atoms of a light element produce far greater effect on a photographic plate or willemite screen than an equal number of the atoms of a heavier element. Thus the parabola corresponding to the hydrogen atom will often be the most intense line on the plate when the amount of that element

present forms less than 1% of the contents of the tube

This has been very clearly demonstrated by Sir J. J. Thomson by substituting an electrical for a photographic method of detecting the positive particles. It must be remembered that as all the particles with which we are dealing carry an electric charge, they can be detected by collecting them in a Faraday cylinder in the way described for the  $\alpha$ -particles in the preceding chapter.

To carry out the experiment a brass plate B (Fig. 15) was substituted for the glass screen Z of Fig. 9. If the brass plate is covered with powdered willemite a series of bright parabolic curves will of course appear upon it when the tube is running somewhat as indicated in Fig. 15a, where three such curves are shown. If a slit SS is cut in the brass plate so as to coincide with one of the parabolas, the particles forming this parabola will pass through the slit and can be collected by a Faraday cylinder F (Fig. 15b) placed immediately behind it. As explained in Chapter III, the rate of charging up of an electrometer connected to the Faraday cylinder will be proportional to the number of particles entering the latter per second, that is to say, to the relative number of molecules in the positive rays which have a mass corresponding to that indicated by the parabola coinciding with the slit SS.

If the slit could be made to coincide successively with each of the different parabolas indicated by the glowing willemite, the relative rates of deflection of the electrometer for the different positions would be proportional to the number of particles of corresponding mass in the positive rays from the discharge. The experiment can be performed much more conveniently without moving the slit by varying the intensity of the deflecting magnetic field,  $H$ . If this is increased it can easily be seen that the corre-

sponding magnetic deflections of the particles will also be increased and the various parabolas will move outwards from the centre of the screen. In this way each of them in turn can be brought to coincide with the parabolic slit SS. It can easily be seen from equations (a) and (b) that if the other conditions of the experiment remain the same the value of  $m/E$  for a given set of particles is proportional to the square of the strength of the magnetic field necessary to deflect them to a given position. Thus from the various rates of deflection of the electrometer corresponding to different values of the magnetic field we can at once determine the relative number of particles in the beam of positive rays corresponding to definite values of the ratio  $m/E$ . In other words, we can determine the relative proportions of the different kinds of atoms and molecules which make up a given beam of positive rays.

On making the experiment it was found that there was practically no movement of the needle of the electrometer connected to the Faraday cylinder except when one of the bright parabolas was made to coincide with the slit. If a fairly narrow slit was used, the appearance and disappearance of a deflection of the electrometer as such a line passed across the slit was surprisingly sharp, and lines quite close together could easily be separated.

Although we can thus perform a quantitative analysis of the beam of positive rays, it cannot be assumed without further experiment that the number of atoms of an element in the beam is necessarily proportional to the quantity of the substance present in the discharge tube. Preliminary experiments, however, seem to indicate that this is very approximately the case, at any rate for the non-metallic elements. If so, this latest modification of the method of molecular analysis will enable us to carry

out not merely a qualitative but also a quantitative analysis of any gas introduced into the discharge tube. The quantitative determination of traces of a gaseous substance too small to be detected by the spectroscope will then have become an accomplished fact.

## CHAPTER V

### THE NATURE AND SIZE OF AN ELECTRON

WE must now turn from these triumphs of experimental skill to some theoretical considerations, and discuss briefly the new views of the atom to which they have given rise. It would be idle to pretend that we have as yet any theory of the structure of the atom which absolutely and completely sums up all the known phenomena of Science. The scientific philosophers of an earlier age hoped that at no very distant date they might be able to include in one or more ponderous tomes all that could be known in the realm of physical phenomena. Looking down the long vistas which the new discoveries have so recently opened up, we expect no such immediate end. We are not yet within sight of a mechanical or electrical theory of the universe wherein all the chemical and physical properties of the material universe shall be explicable in terms of the electrons and their motions. Still, while we cannot say that we have such a theory, there are certain sign-posts pointing out the direction in which we may hope for ultimate success. Even now it is possible to construct "models" of the atom which, however crude and insufficient they may be, enable us to link together many most diverse phenomena.

In the realm of science an insufficient, or even a false, hypothesis is better than none at all, and it will be useful to take the best approximation we can devise to serve us as a clue through the labyrinth of

experimental facts which we have still to consider. At the same time it will be well to point out carefully where we are treading the solid ground of experimental fact and legitimate deduction, and where we rise to the higher but more precarious flights of scientific imagination.

We have seen that electrons are contained in all atoms, and many phenomena lead us to believe that they play a most important part in determining both the chemical and the physical properties of the substance. The question naturally arises, What is an electron? Fortunately to this question also we are able to give some answer. An electron is an atom of electricity free from association with anything in the nature of matter as we know it. It not merely has a charge, it is a charge, and apart from its charge has no existence and no properties, not even that of mass.

The exact proof of this statement has involved long and intricate mathematical analysis. It will, however, be possible, without going at all deeply into these abstruse calculations, to make clear the nature of the proofs advanced, and the experimental evidence upon which they rest.

In the first place, since we have already determined the mass of an electron, we must show that such a moving electric charge will possess mass, a property which we have been accustomed to associate only with what we call matter. The proof follows directly from the ordinary laws of electric and magnetic induction, and was first given by Professor J. J. Thomson in 1881, many years before the discovery of the electron rendered possible any practical application of the result.

Consider a small sphere charged with electricity of either sign moving through space with a velocity  $v$ . We have already pointed out that this moving sphere will be equivalent to an electric current element

coinciding with the path of the particle. By the usual laws of electro-magnetic induction this current element will produce a magnetic field, at a distance  $r$  from the particle, equal to  $ev \sin \theta / r^2$ , where  $\theta$  is the angle between the direction of motion of the particle and the direction of  $r$ . Thus, the moving particle is surrounded not only by an electrostatic field due to its charge, but also by a magnetic field due to the motion of that charge. It will be seen that this field has its greatest value in a direction at right angles to the motion of the particle, and falls to zero in the direction in which the particle is travelling.

It is a well-known fact that a magnetic field is the seat of energy, the energy in a field of strength  $H$  being  $\frac{H^2}{8\pi}$  times the volume. The magnetic energy in a small space of volume  $u$  at a distance  $r$  from our moving charge is thus

$$\left( \frac{ev \sin \theta}{r^2} \right)^2 \frac{u}{8\pi} \text{ or } \frac{ue^2 \sin^2 \theta}{8\pi r^4} v^2$$

The total energy of the magnetic field surrounding the particle is the sum of the energy in all these little volumes, from the surface of the particle away to infinity. The summation of this quantity does not present any difficulties. It is equal to  $\frac{1}{3} \frac{e^2 v^2}{a}$ , where  $a$  is the radius of the sphere.

If  $m$  is the ordinary mechanical mass of the particle, the kinetic energy due to its motion will be  $\frac{1}{2}mv^2$ . In addition to this there is, as we have shown, a quantity of energy due to its charge. The total energy of the moving particle and its charge is thus

$$\frac{1}{2}mv^2 + \frac{1}{3} \frac{e^2 v^2}{a}$$

If we write this in the form  $\frac{1}{2} \left( m + \frac{2}{3} \frac{e^2}{a} \right) v^2$ , and

compare it with the ordinary Newtonian expression for the kinetic energy of a particle  $\left(\frac{1}{2}mv^2\right)$  we see that the particle behaves as if its mass  $m$  had been increased by an amount equal to  $\frac{2}{3}\frac{e^2}{a}$ . This is the extra or "electrical" mass, due to the fact that the particle carries a charge. It is evident that, even if  $m$ , the "mechanical" mass of the particle, is zero, the "electrical" mass due to the moving charge will still persist. Thus, even if our electron is a pure charge unassociated with any mechanical mass, it will still have an electrical mass equal to

$$\frac{2 \times (\text{electrical charge})^2}{3 \times \text{radius}}$$

Since this "electrical" mass is really that of the magnetic field surrounding the particle, it resides not in the particle itself but in the medium surrounding it, that is, in that mysterious fluid which we call the ether. As soon, however, as we attempt to alter the motion of the particle this energy flows into it from all sides, so that, as far as experiments upon the particle itself are concerned, the results obtained are precisely the same as if it resided permanently there.

To make this somewhat novel idea a little clearer we may consider a close and very serviceable analogy, where the mechanism of the extra mass is a little clearer than in the electrical case. If any body is moving through water, or any viscous fluid, it carries with it a certain amount of the liquid through which it is moving. In the case of a sphere, for example, the quantity carried along by the motion of the body amounts to half the volume of the sphere itself. A long cylinder moving at right angles to its own length will carry with it a quantity of fluid equal to its own volume. On the other hand, if it moves in the direction of its own length the fluid entangled

is practically *nil*. Thus, in order to set the body in motion with a velocity  $v$ , we have to supply to it energy enough to give this velocity, not only to the sphere itself, but also to the mass of fluid which it carries with it. That is to say, if  $M$  is the mass of the body itself, and  $M'$  the mass of the attached fluid, the work done in starting the body is  $\frac{1}{2}(M + M') v^2$

In other words, the body will behave as if its mass were increased by the mass of the fluid entangled by it. Just as in the electrical case, this extra mass resides in the surrounding medium, but makes itself apparent at the surface of the body when the motion of the latter is altered in any way.

We may very profitably extend this analogy further in that part of our proof which still remains to be considered, by thinking of our electric field in terms of tubes of electric force. This conception we owe to the genius of Faraday. Untrained in the methods of mathematicians, he found the mere algebraical expression for the laws of electrical attraction both unsatisfying and unstimulating. He felt that if two bodies attracted each other it could only be because of some vital bond between them. Thus he imagined that every positive charge was the beginning of a certain number of tubes of force stretching out through space until, somewhere or other, they ended up on an equal but opposite negative charge.

By assuming that these tubes were in a state of tension so that they tended to shorten themselves as much as possible, and, further, that two similar tubes repelled each other, he was able to give a clear explanation of the various electrical phenomena. Thus the attraction between two oppositely charged bodies was the result of the tendency of the tubes connecting them to contract, the repulsion between two like charges was due to the mutual repulsion

between the tubes of force radiating from each of them. An electric current was the motion of one of the ends of the tubes of force along the conductor, while the magnetic effect in the neighbourhood of the current was due to the motion of the tubes of force through the surrounding medium.

FIG. 16.—DISTRIBUTION OF TUBES OF ELECTRIC FORCE ROUND AN ELECTRON AT REST

The concentration of attention upon the phenomena of currents which marked the latter half of last century tended to throw somewhat into oblivion this conception of Faraday. The recent researches with which we are dealing have, however, found in it a most powerful weapon, and are tending to give to these tubes of force a definite significance and concrete existence of which even their originator perhaps hardly dreamed.

Let us add to the postulates already made by

Faraday this additional assumption, that a tube of force when moving through the ether is able to grip a certain quantity of that subtle fluid, in much the same way that a cylinder carries along with it a definite mass of any liquid through which it moves. For a single charged particle at a considerable distance from all other attracting bodies the lines of force will radiate out in straight lines from its surface, and, if the latter is spherical, the tubes will space themselves evenly around it owing to their mutual repulsion. In section, therefore, they will appear somewhat as in Fig 16.

Suppose this system to be moving through space in the direction OA with a velocity  $v$ . If our analogy with the case of a body moving through water holds, the tubes, like OB, which move at right angles to their length, will grip the maximum amount of the ether through which they are moving, while tubes like OA, which are moving along their length, will carry none. It will thus be seen that the distribution of energy in the field surrounding the particle will correspond exactly with the distribution of energy in the electro-magnetic field of which it is supposed to be a visualisation. The electrical mass of the particle will then be the whole mass of the ether gripped by these radiating tubes.

Now it is a well-known fact that a cylinder moving through a fluid in the direction of its own length is not in stable equilibrium. In accordance with the well-known principle of least action, the cylinder will tend to turn so as to offer the greatest possible resistance to the motion, that is to say, it will tend to set itself at right angles to the direction in which it is being compelled to move. If this holds for tubes of force travelling through the ether, then tubes like OA are not in stable equilibrium, but will tend to turn into the plane of OB, which we may call the equatorial plane. It can be shown from the

principles of electricity that such a tendency does indeed exist. The repulsion between the different tubes will, of course, tend to keep OA in position, and, as this repulsion is very great, at moderate velocities the effect we are considering will be quite negligible. The force, however, tending to displace the tubes increases with the velocity of the particle,

FIG 17—DISTRIBUTION OF TUBES OF ELECTRIC FORCE ROUND A MOVING ELECTRON

so that at speeds approaching that of light there is a very perceptible shifting of the lines of force into the equatorial plane, as indicated in Fig 17. But we have noted that the mass of ether gripped by the tubes in this position is greater than that which they originally held. Thus we arrive at the somewhat startling result that the electrical mass of a particle

is not a constant, but depends—at any rate, at high velocities—upon the speed with which it is moving

We have followed out the theory of the variation of electrical mass from the standpoint of Faraday's tubes of force, because in the first place it gives us at once a clear and vivid picture of the processes which are going on in the field, while in the second place we are being gradually driven to the conclusion that some such entities do play a very important part in the phenomena of the electric field. The fact of the variation of electric mass with the speed, however, does not depend in the least upon the particular way in which we choose to regard the electric field, but is a direct though obscure consequence of the fundamental facts of the science.

The exact relation between the electrical mass of a moving charge and its velocity depends somewhat on the assumptions we make as to the distribution and geometrical configuration of the charge. Thus, starting from different ideas of the shape of the electron and the way in which its charge is arranged, different mathematicians have arrived at somewhat different formulæ for this relation. Fortunately, when these are reduced to figures the differences between the best of them are so small that our experiments are scarcely accurate enough to settle definitely between them. The formula now generally accepted, which was due originally to Lorentz, and which has received independent confirmation from the theory of Relativity, makes—

$$\frac{\text{electrical mass } m \text{ at a velocity } v}{\text{electrical mass } m_0 \text{ for small velocities}} = (1 - \beta^2)^{-\frac{1}{2}},$$

where  $\beta$  is the ratio of the velocity of the particle to the velocity of light

Let us see now how these results assist us to discover the nature of an electron. The total mass of the electron may be made up of two parts: its

mechanical mass, which is constant and independent of the velocity with which the electron is moving, and an electrical mass, which increases with the velocity in the way we have just considered. If the electrical mass of the electron is small compared with its ordinary mechanical mass, then there will be very little variation in the total mass of the electron as the speed is increased. If, on the other hand, the whole of the mass is electrical in its nature, the total mass of the electron should increase at the rate given by the formula on the previous page. If part of the mass is mechanical and part electrical, the rate of increase of the whole mass of the electron with increasing velocity will be somewhere between these two values.

If we substitute numerical values in the equation given above, it will be found that the difference between  $m$  and  $m_0$  is quite inappreciable unless the speed of the particle is very high indeed. Thus, when the velocity is as much as one-tenth that of light, the increase in the electrical mass only amounts to about 1%, while even when the velocity reaches one-third that of light—that is to say, over 60,000 miles per second—the increase in the mass is only about 5%. As this is the maximum velocity attainable in a discharge tube, it might have been thought that the experimental investigation of the variation of mass with speed lay for ever beyond our reach.

Fortunately this is not the case. Experiments have shown that the  $\beta$ -particles from radium, while otherwise similar to cathode rays, travel with velocities enormously greater even than those of the particles in a discharge tube, in some cases approaching within 4% of the velocity of light itself. For speeds such as this the electrical mass should be nearly three times its ordinary value, and thus, by careful experiments on these particles, we might well hope to put to the test the theories we have propounded.

FIG 18—KAUFMANN'S APPARATUS FOR DETERMINING THE MASS OF A  $\beta$ -PARTICLE

Such experiments have been made with exquisite skill and care by Kaufmann. In principle the methods he employed were identical with those already described. The  $\beta$ -particles given out by

a small quantity of radium placed at R (Fig 18), passed through a fine hole in a lead screen at A,

FIG 19—KAUFMANN'S EXPERIMENTAL CURVE FOR THE ELECTRIC AND MAGNETIC DEFLECTION OF THE  $\beta$  RAYS FROM RADIUM

before finally falling on a photographic plate at P. Before reaching the hole at A the particles passed between two parallel plates, which could be very carefully adjusted by means of a series of levelling

screws, and which were charged to a high difference of potential. The whole of the apparatus was placed between the poles of a strong electro-magnet N, S, arranged so that the electric and magnetic fields were parallel to each other and therefore the corresponding deflections they produced at right angles to each other, exactly as in Professor Sir J. J. Thomson's experiments on the positive rays. Apart from the differences in velocity all the  $\beta$ -particles are identical. Thus, for every value of the velocity  $v$  there is only one corresponding value for the mass  $m$ . Hence the beam of rays is drawn out on the plate into a single curve (Fig. 19), each point on which corresponds to particles with a particular mass and speed.

This curve can be measured up with a micrometer in exactly the same way as has been described for the positive ray curves, and the mass and speed of the particles deduced by equations (c) and (d) (Chapter IV). The values of the constants  $k_1$  and  $k_2$  for the apparatus were very accurately determined, as were also the strengths of the electric and magnetic fields. In this way Kaufmann obtained results which he regarded as being accurate to within 1.5%, a very notable achievement.

Some of the results obtained are given in Table V. The first column of the table gives the velocity of the particles, the second the value of  $\beta$ , the ratio of the velocity of the particle to the velocity of light. In the third column we have Kaufmann's experimental values for the ratio of the whole mass of the particles to their mass at small velocities. In reducing his experimental results Kaufmann used, not the formula of Lorentz, but a rather more complex one due to Abraham. The last column gives the theoretical value of this ratio, deduced from Abraham's equation, on the assumption that the whole of the mass is electrical.

It will be seen how very closely, all things

considered, the two sets of figures agree. The experimental values for the ratio  $m/m_0$  increase, if anything, even more rapidly than theoretical. This would imply that, if anything, the mechanical mass of the electron is negative, which is, of course, an impossibility. A re-calculation of the original figures on the Lorentz formula gives even better agreement.

TABLE V

Kaufmann's values for the variation of the mass of a  $\beta$ -particle with change of velocity

Velocity of the $\beta$ particle	$\beta = \frac{\text{velocity of particle}}{\text{velocity of light}}$	Experimental value of $m/m_0$ for the $\beta$ particle	$m/m_0$ for Abraham's equation

We have now discussed the evidence for our original statement that the whole mass of the electron is electrical in origin and due entirely to the charge it carries. Granting this conclusion, we can at once determine the dimensions of the electron, and so complete our knowledge of its properties.

We have seen that the electrical mass of a charge  $e$  for moderate speeds is equal to  $\frac{2}{3} \frac{e^2}{a}$  where  $a$  is the

radius of the space occupied by the charge. The mass of an electron is  $8.8 \times 10^{-28}$  gms, while the value of the charge it carries is  $1.57 \times 10^{-20}$  units. Substituting these values in the formula we find that the radius of an electron is  $1.87 \times 10^{-11}$  cms.

We have stated elsewhere that the radius of an atom is of the order of  $10^{-8}$  cms, and have attempted to form some idea of the exceeding smallness of this magnitude. We may now say that small as the atom is, the electron is so much smaller that the electron bears to the atom which contains it very much the same relation as a pea to a cathedral.

## CHAPTER VI

### THE STRUCTURE OF THE ATOM

THE discoveries which we have been describing at once gave rise to fresh speculations as to the nature of matter and the constitution of the atom. The proof afforded by chemistry that all the myriad substances around us were built up from some seventy or so different elements had indeed effected a very marked reduction in the apparent complexity of the material world, but it had always been felt that the reduction was not sufficient, and that seventy different and independent kinds of atoms was far too many to go to the construction of a well-organised universe. Previous attempts to reduce this chaos to scientific order had languished for want of any kind of experimental basis, though on the other hand the ever-increasing proofs of order supplied by the periodic classification of the elements made it increasingly certain that some structural connection of the closest kind must exist between the different elements. The discovery of the electron and its properties, by affording certain knowledge of at least one of the constituents from which the atoms of the different elements were constructed, opened the way to a fresh flood of daring speculations.

We have seen that the whole mass of the electron is due to the charge which it carries. The thought at once suggests itself. Are there, indeed, two kinds

## THE STRUCTURE OF THE ATOM 83

of mass, or is all mass electrical in its origin? The mass of a negative electron is about  $1/1770$  part of the mass of a hydrogen atom. Neglecting the positive part of the atom it would require about 1770 elections to make up the mass of a single hydrogen atom. This, of course, is by no means an impossible number considering the smallness of the electron in comparison with the size of the atom, and speculations along these lines were very freely indulged in for a time. In this case, however, experiment failed to confirm the bold conjecture. The number of electrons in the atom has been determined, at any rate approximately, and affords no support for such a theory.

As this number of electrons in the atom is obviously a matter of very fundamental importance for the construction of any rational theory of atomic structure, we may perhaps be allowed to describe, very briefly, one of the methods by which attempts have been made to determine it. Consider a single electron flying through a sheet of metal. With the huge velocity which it possesses a sheet of aluminium, say  $\frac{1}{4}$ th mm thick, is not a very serious obstacle to a  $\beta$ -particle. Neglecting for a moment the positive charge which keeps the atom together, the various atoms which our particle encounters must present to the particle the appearance of a series of large chambers, empty save for a certain number of particles, minute in comparison with the atom, and similar to itself.

At a considerable distance these fixed electrons will have little effect on the moving corpuscle. If, however, in its flight it approaches one of them closely it will be repelled, as the two particles each carry a negative charge. The nearer it approaches the greater will be the repulsion, and the further the moving particle will be deflected from its original path. We may call this a collision. It is, in fact,

the same sort of collision as we imagine to take place between two gas molecules. The direction in which the particle will be deflected will be perfectly arbitrary, and a second collision may actually undo the work of the first. On the whole, however, the greater the number of collisions the greater will be the deflection, and it is not beyond the possibilities of mathematics to determine the most probable effect of a given number of these deflections. The problem is indeed mathematically equivalent to the well-known theorem of the drunkard's walk. Suppose a drunkard walks so many yards before falling down, and after each fall, having lost all sense of locality, sets out again in some new and arbitrary direction, at what distance from his starting-point will he be most likely to be found after a given number of falls? This problem, under a somewhat different title, has been solved by Lord Rayleigh in that marvellous compendium of mathematical physics, the "Theory of Sound."

If then we find experimentally the most probable deflection of a  $\beta$ -particle after passing through a certain thickness of solid matter, we can deduce the number of collisions it has made in its passage through the solid, and hence the number of electrons in unit volume of the substance. Since the number of atoms per cubic centimetre of any substance can readily be deduced from the data given in Chapter III, the number of electrons in each atom can at once be determined.

A series of experiments upon these lines was some time ago performed by the author. By various experimental devices, which it would take us too far from our course to describe, the mean angle through which an originally parallel pencil of  $\beta$ -rays was scattered in passing through sheets of various substances was determined. By experimenting on sheets of different thicknesses the author was able

to show that the mathematical treatment outlined above was applicable to this particular case, and hence to deduce the number of electrons in the atoms of the various elements experimented upon.

The matter is, perhaps, hardly so simple as we have described it. We have neglected so far the effect of the positive electrification which we know must be present in the atom if the latter is to be electrically neutral. This will exert a certain attraction on the flying electrons.

At the time the experiments were made very little was known as to the nature and distribution of the positive charge in the atom. The most popular conception (adopted first by Lord Kelvin and accepted in the main probably because it lent itself most readily to mathematical treatment) was that the positive charge was distributed uniformly over a sphere co-extensive with the atom itself. On this assumption the author's results would indicate that the number of electrons in an atom is almost exactly three times its atomic weight. That is to say the hydrogen atom would contain just three. If, however, we go to the other extreme and assume that the positive charge forms a sort of nucleus at the centre of the atom, with the electrons revolving around it like the rings of the planet Saturn, the number of electrons in the hydrogen atom works out at unity, while for other elements the results indicate that the number of electrons per atom is even smaller than the atomic weight.

As we shall see shortly, this nuclear or Saturnian theory of the positive charge is almost certainly correct, and we must admit that the number of electrons in the atom of an element is less than its atomic weight. This result has been confirmed by later experiments on the scattering of Röntgen rays in their passage through matter. It can be shown that when a Röntgen pulse passes across an electron, it

causes the latter to emit secondary waves which radiate out in all directions round the electron. It is obvious that the intensity of the secondary radiation coming from a given piece of matter will be proportional to the number of radiating systems, that is of electrons, which it contains. A comparison of the relative intensities of the original and the scattered radiation will enable us, therefore, to determine the number of electrons present. The experiments are not particularly easy, but the results indicate that, with the exception of the hydrogen atom, which contains a single electron, the number in the atom is approximately equal to one-half the atomic weight of the element. These experiments have the additional advantage that their result is independent of the assumptions made as to the nature of the positive part of the atom.

We may also attack the problem indirectly (and it is one of such importance that we cannot have too much evidence on the subject), by determining the magnitude of the positive charge on the atom. Since the atom as a whole is certainly neutral, it is obvious that the charges on the electrons in the atom must be equal and opposite to that on the positive part of the system. Hence, if we can determine the latter, the number of electrons necessary to neutralise it is at once known.

The positive portion of the atom can be investigated in much the same way as that employed by the author for finding the number of negative electrons, using as an exploring instrument not the  $\beta$ - but the  $\alpha$ -particles from some radio-active substance. On account of their greater mass and energy these  $\alpha$ -particles will be practically uninfluenced by the comparatively light electrons, but will be repelled by the positive mass of the atom, and thus deflected from their original paths to an extent which will increase with the magnitude of the

charge upon it. In many ways the  $\alpha$ -particle is most suitable for experiments of this kind, since owing to its greater energy it is possible to determine the track of a single  $\alpha$ -particle, while the  $\beta$ -particles can only be treated in mass. The method adopted by Geiger, to whom the experiments are due, was to allow a parallel pencil of the  $\alpha$ -particles to pass normally through very thin sheets of metal foil, and then to fall upon a fluorescent screen, in much the same way as that used by Regener in his counting experiments. Each  $\alpha$ -particle registered itself upon the screen by a single flash of fluorescence, and the distance by which it had been deflected from its original path in passing through the metal foil could easily be determined. The experiments are very tedious, involving the counting of many thousands of scintillations, and the authors do not claim an accuracy of more than 20 per cent. Within these limits, however, the results certainly indicate that the number of atomic units of positive charge on the positively charged part of the atom is approximately equal to one-half the atomic weight of the element. Since the charges on the electrons exactly neutralise this, the number of electrons in the atom again works out at about one-half the atomic weight.

The agreement of the results obtained in such diverse ways is quite satisfactory, at any rate as to the order of the number which we are seeking, though in view of the great importance of the subject determinations of greater accuracy are much to be desired and will no doubt shortly be forthcoming. In the meantime the results already obtained are quite sufficient to dispose of any hope which might have been entertained of accounting for the mass of the atom by the properties of the electrons which it contains. The mass of the electrons must be, even at the highest estimate, a quite inappreciable fraction of the total mass of the atom.

There still remains, however, the possibility that all mass is electrical in origin, but that it is connected, not with the negative, but with the positive portion of the atomic charge. If the formula for the electrical mass of a charged particle be examined, it will be seen that for a given charge the mass is inversely proportional to the radius of the sphere upon which it is concentrated. If we suppose that the positive charge contained in the hydrogen atom is concentrated upon a sphere having only  $1/1770$  of the radius of the negative electron its mass would be 1770 times as great as that of the electron, that is to say, it would be equal to that of the hydrogen atom, and no other source of mass would be required. At the time when this volume was first published evidence for this view was sadly lacking, and the belief expressed in the electro-magnetic origin of all mass was but an unsupported declaration of the scientific faith that all the varied phenomena with which we have to deal are manifestations of some single principle or essence which underlies them all. In the case which we are now considering, of the electro-magnetic origin of all mass, this declaration of faith has received marked confirmation in some ingenious experiments which have been carried out in the laboratory of Sir Ernest Rutherford.

We have already seen what information can be extracted from experiments on the passage of  $\alpha$ -particles through thin sheets of solid matter. In this case the deflecting atoms in the sheet are bound in their places by the strong forces of tenacity and cohesion. They are therefore practically immovable, and only the course of the  $\alpha$ -particle is changed. Suppose, however, that instead of passing the  $\alpha$ -particle through a solid we allow it to pass through some gas such as hydrogen, for example. The  $\alpha$ -particle, as we have seen, consists of a doubly charged atom of helium, and therefore has a mass of about four

times that of the hydrogen atom. It is obvious that if such a particle collides with one of the atoms in the hydrogen gas, the latter, being perfectly free to move and not being bound in position by any of the forces which keep the atoms in a solid fixed, will be driven forward with a considerable velocity, in much the same way that one billiard ball is set in motion by the impact of another. The velocity with which the hydrogen atom will begin to move depends on its mass (which is known) and the force of the impact. Now the force of repulsion between two positive charges, such as those carried by the  $\alpha$ -particle and the positively charged portion of the hydrogen atom, varies inversely as the square of the distance between their centres. Thus, the nearer the two particles approach during the collision the greater will be the force and the greater the velocity with which the hydrogen atom will move. If this velocity can be measured, it becomes a mere matter of calculation to determine how closely the two positive charges must have approached during their collision for the force between them to become sufficiently large to produce the velocity actually found.

On making the experiments it was found that the velocity imparted to the hydrogen atoms by the impact of the  $\alpha$ -rays was sufficient to enable them to cause a scintillation upon a fluorescent screen, and their track could thus easily be determined. Their velocity was deduced by comparing their penetrating powers with that of  $\alpha$ -particles of known velocity.

The velocity given to the hydrogen atoms by the impact of the  $\alpha$ -particles was found to be very large. In fact some of the hydrogen atoms were found to have acquired a speed of more than 16 times that of the  $\alpha$ -particles themselves. In order that the repulsion between the positive charges on the hydrogen and the helium atoms should be suffi-

cient to produce such a velocity it is necessary that their centres should approach to within a distance of  $1.7 \times 10^{-13}$  cm. Since the two centres can approach within this distance, the positive charges on the atoms of hydrogen and helium must be concentrated on nuclei the sum of the radii of which does not exceed  $1.7 \times 10^{-13}$  cm, a distance which is less than the radius of a single negative electron. We thus arrive at the surprising result that, small as is a negative electron, the positive charge on a hydrogen atom is concentrated on a nucleus which is smaller still.

The method of the experiment gives obviously only a maximum estimate of the radius of the positive nucleus, the actual radius may, of course, be much smaller than this. At any rate, the fact that two atoms can approach within such a remarkably small distance would seem to make it quite impossible that there can be anything in the atomic structure save the two elements of positive and negative electricity which our experiments have revealed to us. It may be noted in passing that as the mass of the hydrogen atom has been proved to be concentrated in a nucleus whose radius certainly does not exceed  $0.8 \times 10^{-13}$  cm, the density of this nucleus must be of the order of  $10^{18}$  gm per c.c. It seems impossible to conceive that a density of this magnitude can be due to anything save electromagnetic action.

Our ideas of the structure of the atom are now becoming clear. An atom consists of a central nucleus of small dimensions in which practically the whole of the mass of the atom resides. This nucleus is positively charged as a whole, and the mass of the nucleus is most probably entirely due to the charge which it carries. Outside this nucleus, and probably at comparatively considerable distances from it, are sufficient negative electrons to make the system as a whole electrically neutral. These elec-

trons occupy the space which we know as the "volume" of the atom, not by filling it with their bulk, but either by moving about in it, in somewhat the same way as the molecules of a gas occupy the space in which they are confined or by the electrical forces which they exert. Our different probings of the atom have revealed the presence of nothing apart from these two sets of particles. We must therefore picture the atom as a sort of void in which a comparatively few, minute, negatively charged planets circulate around a small positively charged sun.

The number of the elections which make up the planetary system of the atom of a given element is, as we have seen, not yet determined with the certainty which is desirable, but is, at any rate, approximately one-half the atomic weight, except in the case of hydrogen, which almost certainly contains only one. If a table of the elements is consulted in which the elements are arranged in order of their ascending atomic weights, and if the elements are numbered consecutively, beginning with hydrogen as number one, it will be noticed that the number of the element on the list, the "atomic number," as it is called, is very approximately equal to one-half of its chemical atomic weight. Van der Broek has made the ingenious suggestion, which is almost certainly correct, that the number of electrons surrounding the nucleus of a given atom is exactly equal to its atomic number, and that consequently the positive charge on the central nucleus is also equal to the atomic number multiplied by the atomic unit of charge. Thus a hydrogen atom would consist of a single electron and a single positive charge. The atom of helium would have two electrons, and a doubly charged nucleus, while lithium would have three elections, beryllium four, and so on. Thus each element would differ from the one immediately preceding it in the table by containing one more

electron in its planetary system and one more unit of charge on its central nucleus. The atoms of each element would differ from those of the element immediately preceding it in the table in the simplest possible way, the electrons and the central charge each increasing by unitary steps. It would follow from this that, at any rate in the earlier part of the table, all the elements possible, on the system which we are discussing, actually exist and have been discovered. The facts of the periodic classification of the elements certainly warrant this assumption.

Before passing on to consider the structure and arrangement of such systems, and endeavouring to discover how the known physical and chemical properties of the elements can be deduced from such a structure, we may say one further word about the central nucleus itself. The nucleus in the hydrogen atom contains, as we have seen, a unit of positive charge the radius of which is certainly less than  $10^{-18}$  cm. In all probability this hydrogen nucleus is the long sought for positive electron, in which case the hydrogen atom would consist simply of one negative and one positive electron forming a sort of unitary electrical doublet. The nucleus of the next element, helium, as a whole, carries twice the charge of the hydrogen nucleus. On the other hand, it has very nearly four times the mass. The simplest explanation of this discrepancy is that the helium nucleus is complex, containing four positive electrons, which would give it the necessary mass, but that, as far as its external field is concerned, two of these units of positive charge are neutralised by the presence in the nucleus of two negative electrons.

Such nuclear electrons, if they exist, will of course be additional to those which we have described as the planetary electrons and whose number is equal to the atomic number of the atom. The size of the nucleus is too small for it to act otherwise than as a

single particle in the experiments which we have been describing. The presence of negative electrons within the central nucleus seems to be demanded by the phenomena of radio-activity. It seems impossible to conceive how the enormous velocities with which the electrons which make up the  $\beta$ -rays are ejected from the atoms of radio-active substances could be generated by the comparatively weak forces between the positive nucleus and its outer sphere of electrons. They are much more readily accounted for if we suppose them to be due to the very tense forces which must exist in a central nucleus containing such comparatively numerous charges in such an infinitesimal space.

The fact that the material particles ejected by radio-active substances (the  $\alpha$ -rays) invariably consist of atoms of helium would certainly suggest that the helium nucleus is present as such in the nuclei of elements of higher atomic weight, and various arrangements of helium nuclei, or of helium and hydrogen nuclei combined, have been proposed and have met with some support on spectroscopic grounds. The problem is one for the future. In any case the nucleus is so small in dimensions that its internal arrangements can make but little difference to the properties of the atom as a whole. Its functions appear to be firstly to provide the mass of the structure, and secondly, by its electrical attraction, to hold together within the atom the swarm of electrons which form its outer or planetary system.

Electrically speaking the positive nucleus is so small that it may almost be regarded as acting as a point charge. It is therefore the arrangement of the negative electrons which surround it which will determine the electrical forces exerted by the atom and therefore its chemical and physical properties. Moreover, the negative electron is very mobile. It is in fact entirely owing to its mobility that we know

so much about it, and, as we shall see, this mobility has very important and far-reaching effects in determining the characteristics of the atom

The problem of the arrangement of a number of electrons around a central positively charged nucleus presents mathematical difficulties of a very grave kind, which at present seem to be insoluble by the accepted principles of classical mechanics and electromagnetic theory. By introducing new assumptions and fresh mechanical conceptions Bohr has succeeded in constructing simple atoms and molecules out of positive and negative nuclei with a certain amount of success, but his assumptions are at present so unsupported and would seem to involve such extensive changes in the basic principles of science that they have not yet received general acceptance, and his results must be regarded as interesting suggestions rather than as actual physical facts.

The problem becomes much simpler if we assume that the positive electrification occupies the whole volume of a sphere co-extensive with the atom, and that the electrons are embedded in it like raisins in a pudding. An atom of this kind was suggested by Lord Kelvin, and has been worked out in detail by Sir J. J. Thomson. The two problems are sufficiently akin to afford us some confidence that the solutions in the two cases will be similar in form, though of course differing numerically, while the results themselves are sufficiently suggestive to repay the closest study.

The grouping of a number of electrons in a sphere of positive electrification which is just sufficient to neutralise their charges at points outside the sphere has been investigated theoretically by Professor Sir J. J. Thomson. A single electron if at rest will place itself at the centre of the sphere, or if in motion will describe a circle around that point with a radius depending on its velocity. Two electrons

would occupy the opposite ends of the diameter of a circle whose radius is equal to half the radius of the positive sphere, while three electrons would arrange themselves at the points of an equilateral triangle. The arrangement of four electrons at the corners of a square is, however, not a stable grouping if the ring of electrons is at rest, but becomes possible if they are revolving round the centre with a speed which exceeds a certain critical value. If their velocity falls below this the system collapses into a tetrahedron with an evolution of energy.

The determination of the arrangement of any number of electrons in a space of three dimensions becomes at first difficult and finally impossible. A few cases have, however, been worked out. Thus six electrons would arrange themselves at the corners of a regular octahedron, but, on the other hand, the arrangement of eight at the corners of a cube is not stable, and will collapse into two tetrahedra, one inside the other, unless we station at least one other electron within it. We are thus brought face to face with one of the most important generalisations in electron grouping, namely, that it is quite impossible for any system to make a large display of electrons near its surface without a corresponding stock within. The presence of a given number of electrons near the outside of the atom demands that there shall be a certain definite number of electrons within in order that the system may be stable. To use a commercial metaphor, an atom cannot have all its goods in the shop window. Otherwise there will be inevitable collapse into some less pretentious system.

The analysis becomes simpler, and leads to the same general results, if we consider the electrons as confined to a single plane—a supposition which is not altogether without justification on experimental grounds. This case has the further advantage that it can be studied experimentally in a variety of ways

Of these the very beautiful experiments of Mayer, though designed for quite other purposes, are perhaps the simplest to reproduce

A large number of needles are magnetised together in a solenoid, and are floated vertically in a basin of water by pushing all their (say) north poles into small corks, their south poles being at the same depth below the water. These latter repel each other, just as do the electrons, according to an inverse square law. To represent the action of the positive sphere we may place a strong electro-magnet beneath the bowl with its north pole upwards. It can be shown that the attraction of this magnet for the tiny south poles is (for the horizontal plane in which alone they are able to move) approximately proportional to their distance from a point immediately above the pole. Fig 20 is a photograph showing ten of these small magnets. It will be seen that they are arranged in two rings of seven and three respectively. The attracting electro-magnet is concealed below the board.

On making the experiment it is found that the greatest number of magnets which we can have in an empty ring is five. If a sixth is added the ring breaks up, the magnets gradually settling down into an arrangement of five on the outside with one in the middle. The number which must be placed in the middle rapidly increases with the number in the outer ring. Thus an outer ring of twelve requires at least eight inside, and one of thirty no less than one hundred and one for stability to be possible. As these inner magnets are subject to exactly the same laws as the outer ones, the whole system, whether of magnets or electrons, splits up into a series of concentric rings, with a perfectly definite number of particles in each.

A complete mathematical solution has been obtained by Professor Thomson. Table VI contains

## THE STRUCTURE OF THE ATOM 97

his results for the model atoms in which the number of elections is not more than fifty-two I would point out very emphatically at this point that no stress must be laid on the exact numbers given in this Table. The simplifications we have made are too many to render it even possible that these

FIG. 20—A "MODEL" ATOM

arrangements represent actual atoms of any real substance. Neither does the weight of the argument rest on any numerical relations between the numbers of elections in the different rings. The general law of electron grouping enunciated above when discussing three dimensional systems is amply sufficient for all that follows, and is all we have at

present any right to make. It is, however, of the greatest assistance in following the arguments to clothe our abstract principles in concrete form, and to consider some definite case where the relationships can be expressed in numerical form. The system chosen is the simplest for the purpose.

The first row in Table VI contains, with these limitations, the "atoms" for which there is only one ring of electrons, the second those with two, and so on, the upper number being in each case that contained in the outer ring. Thus 11, 5, 1, which commences series C, implies that this atom contains an outermost ring of eleven electrons with an inner ring of five and a single electron at the centre. Remembering that the number of electrons in the atom is proportional to the atomic number, it will be seen that this Table represents a series of model elements arranged according to their ascending atomic weight.

A very cursory glance at this Table, at once reveals a very striking similarity to Mendeleef's periodic classification of the elements (see page 111). Thus, for example, if we assign any chemical or physical property to the existence in the atom of an arrangement of electrons such as (5, 1) this property will disappear as we pass along the series to atoms with different groupings, and consequently different properties. Proceeding still further, however, we come to a place where the original grouping (5, 1) is restored with the addition of an extra outer ring of eleven electrons (11, 5, 1).

This grouping again disappears as we pass along series C, to reappear again with an extra ring of fifteen at the beginning of series D, and with a further ring of seventeen in series E.

Thus any property associated with a given grouping of electrons will recur again and again at intervals, as the number of electrons in the model

atom is increased. It can hardly be necessary to point out how closely this resembles the arrangement of the elements according to atomic weight where the properties of the element sodium, for example, disappear as we proceed to elements of higher atomic weight, only to make their appearance again with slight modifications when we arrive at the element potassium.

There are many other resemblances which may be pointed out between the periodic table and our scheme of electrons. In the first place it will be seen that in the same group the atoms of series D and E have four rings in common with each other, while those in series B and C have only two. The elements of higher atomic weight will resemble each other more closely than the elements of lower atomic weight. This, again, is a commonplace of the periodic classification. Further, it will be seen that at certain places in the table the groupings are in rapid change, while at others the configuration alters much more slowly. This again corresponds very closely with what actually occurs in the arrangement of the elements, where, starting, for example, at sodium, the alkaline properties gradually disappear as we pass through magnesium and aluminium, to be replaced by acid ones at sulphur and chlorine. As we proceed further, however, there is a sudden recurrence of the alkaline properties at the next element, potassium.

It may be asked, what properties can be associated with a grouping of electrons in a sphere of positive electrification? If we are on the right track, we must expect sooner or later to be able to interpret every phenomenon associated with the atom in terms of such a system. But this is a far cry, and it must be confessed that our present knowledge does not extend very far in this direction. We can, however, suggest several important pro-

## THE STRUCTURE OF THE ATOM 101

perties which may, and one or two which can be proved to be the result of causes of this kind

In the first place, we may almost certainly include all those forces of cohesion, adhesion, and the like which go by the name of molecular—those attractions which, quite insensible at any appreciable distance, are yet at distances comparable with the diameter of a molecule strong enough to rivet together the atoms and molecules in a solid so firmly that in some cases it requires stresses of many tons to the square inch to drag them asunder. Since these molecular forces determine tenacity, elasticity, and melting point for solids, and surface tension and

FIG. 21.—DIAGRAM TO ILLUSTRATE COHESION

vapour pressure for liquids, it will be seen that a very considerable and important set of properties are thus brought within the scope of our hypothesis.

The most probable, and, indeed, at present, the only explanation of these molecular attractions, is that they represent the resultant force between the different parts of the two electrical systems which make up the atoms. Let us take as an illustration a very simple concrete case. Suppose the black dots in Fig. 21 represent the outer rings of electrons in two adjacent atoms, and that the effect of the positive electricity may, for the sake of simplicity, be regarded as concentrated in the white circles between them.

Since each of the atoms, as a whole, is electrically

neutral, the attractions and repulsions between the different parts at any distance which at all greatly exceeds the diameter of the atom will be vanishingly small. If, however, as in the illustration, the two atoms are brought so close together that their distance is only a fraction of this diameter, this is no longer the case. It can readily be shown that the atoms will turn so that a negative electron in the one is faced by the positive portion of the other. There would thus be an attraction between them which would increase with great rapidity as the distance between the atoms was diminished. The law of force would thus be similar to that actually found for these molecular forces.

The magnitude of the forces obviously depends on the number and arrangement of the electrons in the atom. A complete theory of cohesion is not possible in the present state of our knowledge. There is little doubt that it will be found to proceed on lines not very different from the explanation suggested above.

Although our methods of analysis do not enable us to pursue this problem further, another very important characteristic of the atom, namely, its emission spectrum, has proved more amenable to investigation. The evidence obtainable from a study of spectral lines is so important that we shall deal with it more fully in a later chapter. For the present it may be noted that, before the electron had been isolated and its properties determined by direct experiment, it had been shown by Lorentz that the systems emitting the vibrations which constitute ordinary light were negatively charged particles, and further, that the ratio of the charge to the mass was of the order of  $1.7 \times 10^7$ . It was also shown that these same electrons were the cause of the absorption of light and its dispersion in transparent media. Thus, practically the whole range

of optical phenomena of the atoms are due to the electrons which they contain. This point is so important that we shall return to it in a separate chapter.

The results which we have been using to illustrate the nature and results of electron grouping were deduced on the assumption that the positive electrification is spread over the whole of the atom, and the actual numbers therefore have no significance. The main principles of grouping, however, in all probability hold equally well for the atom with a central nucleus. So far as they have gone, Bohr's results would indicate that in this case also the electrons arrange themselves in certain stable ring systems or groups, and that to make these groups stable a certain number of electrons must be contained within them, exactly as in the atomic systems of Sir J. J. Thomson. We may therefore accept these as the two main principles governing electron grouping.

Now it is an immediate consequence of these principles that the electrons in the atom are not all held in the same way or with the same retaining force. The tendency is, as we have seen, for the electrons to arrange themselves in a series of stable rings around the central nucleus, making the atom appear like a model of the planet Saturn on an infinitesimal scale. These rings of electrons together with the nucleus itself form the framework of the atom, the disruption of which would mean the disintegration of the whole atom into some other and simpler kind of structure.

The formation of a ring, however, requires the fulfilment of certain very definite conditions. There must, for example, be a certain definite number of electrons within the ring to ensure its stability. Thus it will happen in general that there will be a certain number of electrons in the atom in excess of those which can be combined into stable ring

systems, and which will therefore be a far less integral part of the atom than those which are so combined. Being held only by the attraction of the central nucleus, and having no permanent ties with the rest of the structure, they will at once be more free to move about in the atom, and less strongly united to it, while their removal from the atom altogether might be effected without any serious derangement of the atomic structure. The existence of such comparatively free electrons is not a mere theoretical postulate or deduction. It is required by phenomena as diverse as the ionisation of gases, the conductivity of metals, and the dispersion of light. Experiments on optical dispersion have shown that the number of these comparatively mobile electrons in a given quantity of matter is not many times greater than the number of atoms present, and that they thus form only a fraction of the whole number of atomic electrons, similar results are obtained from a consideration of the number of free electrons in a metallic conductor. We shall see later that these mobile electrons determine the chemical properties of the atom. They are therefore usually spoken of as *valency* electrons, or occasionally, from their action on light, as the *dispersional* electrons.

Let us suppose, to put the matter in its most general terms, that for an outer ring of  $A$  electrons we require  $a$  electrons within for stability, while a ring of  $A + 1$  requires  $b$  electrons. Consider an atom with an outer ring of  $A$  electrons having  $n$  other electrons within it where  $n$  is some number greater than  $a$  but less than  $b$ . By suitable means we may extract from this atom a number of electrons equal to  $n - a$  without destroying the equilibrium of the outer ring  $A$ . If, however, we succeeded in extracting one further electron the system would become unstable and the atom would collapse.

Now we know that any real atom is a very stable

structure indeed. Certain atoms, it is true, owing to circumstances which we shall have to consider later, spontaneously break up into simpler substances, but there is no known agency by which we can bring about the dissolution of an atom of ordinary matter. The phenomena of radio-activity have furnished the clue to our failure: the energy required is too great. On the other hand, the energy required to extract single electrons from a neutral atom has been determined experimentally and is triflingly small. A single  $\alpha$ -particle, for example, has sufficient energy to produce many thousands of ions. Thus the work required to reduce the number of electrons in the atom below the critical value  $a$  would be out of all proportion greater than that necessary to extract the electrons above this number. In effect, the value  $a$  would be a barrier which we could not overstep.

Similarly, we could add to the atom sufficient electrons to make up its number to  $b$ , without inducing any change in the atomic structure. Beyond that point a further electron would necessitate an outer ring of  $A + 1$  electrons, with a consequent rearrangement of the whole atomic structure.

The two critical values  $a$  and  $b$  thus constitute, as it were, barriers which we cannot pass. We may extract  $n - a$  electrons at most, that is to say, the atom possesses  $n - a$  free or valency electrons, or, on the other hand, we might conceivably add  $b - n$  electrons to the system. More than this we cannot achieve. The sum of these two quantities, which is  $b - a$ , is a constant for all the elements having a ring of  $A$  electrons. This is an important point to which we shall return.

We can now apply these results immediately to the known series of the elements. It is obvious that an atom in which all the electrons were combined into stable systems would present very marked and peculiar characteristics. In the first place, since it

systems, and which will therefore be a far less integral part of the atom than those which are so combined. Being held only by the attraction of the central nucleus, and having no permanent ties with the rest of the structure, they will at once be more free to move about in the atom, and less strongly united to it, while their removal from the atom altogether might be effected without any serious derangement of the atomic structure. The existence of such comparatively free electrons is not a mere theoretical postulate or deduction. It is required by phenomena as diverse as the ionisation of gases, the conductivity of metals, and the dispersion of light. Experiments on optical dispersion have shown that the number of these comparatively mobile electrons in a given quantity of matter is not many times greater than the number of atoms present, and that they thus form only a fraction of the whole number of atomic electrons, similar results are obtained from a consideration of the number of free electrons in a metallic conductor. We shall see later that these mobile electrons determine the chemical properties of the atom. They are therefore usually spoken of as *valency* electrons, or occasionally, from their action on light, as the *dispersional* electrons.

Let us suppose, to put the matter in its most general terms, that for an outer ring of  $A$  electrons we require  $a$  electrons within for stability, while a ring of  $A + 1$  requires  $b$  electrons. Consider an atom with an outer ring of  $A$  electrons having  $n$  other electrons within it where  $n$  is some number greater than  $a$  but less than  $b$ . By suitable means we may extract from this atom a number of electrons equal to  $n - a$  without destroying the equilibrium of the outer ring  $A$ . If, however, we succeeded in extracting one further electron the system would become unstable and the atom would collapse.

Now we know that any real atom is a very stable

structure indeed. Certain atoms, it is true, owing to circumstances which we shall have to consider later, spontaneously break up into simpler substances, but there is no known agency by which we can bring about the dissolution of an atom of ordinary matter. The phenomena of radio-activity have furnished the clue to our failure: the energy required is too great. On the other hand, the energy required to extract single electrons from a neutral atom has been determined experimentally and is triflingly small. A single  $\alpha$ -particle, for example, has sufficient energy to produce many thousands of ions. Thus the work required to reduce the number of electrons in the atom below the critical value  $a$  would be out of all proportion greater than that necessary to extract the electrons above this number. In effect, the value  $a$  would be a barrier which we could not overstep.

Similarly, we could add to the atom sufficient electrons to make up its number to  $b$ , without inducing any change in the atomic structure. Beyond that point a further electron would necessitate an outer ring of  $A + 1$  electrons, with a consequent rearrangement of the whole atomic structure.

The two critical values  $a$  and  $b$  thus constitute, as it were, barriers which we cannot pass. We may extract  $n - a$  electrons at most, that is to say, the atom possesses  $n - a$  free or valency electrons, or, on the other hand, we might conceivably add  $b - n$  electrons to the system. More than this we cannot achieve. The sum of these two quantities, which is  $b - a$ , is a constant for all the elements having a ring of  $A$  electrons. This is an important point to which we shall return.

We can now apply these results immediately to the known series of the elements. It is obvious that an atom in which all the electrons were combined into stable systems would present very marked and peculiar characteristics. In the first place, since it

contains no free or dispensional electrons its optical dispersion would be very small, while for the same reason it would possess no electrical conductivity. Again, since all the electrons are combined into closed rings it would exert practically no electric force outside its own radius, and would therefore exert little or no attraction on surrounding atoms. Thus it would form no chemical compounds, not even combining with other atoms of its own kind to form molecules, and for the same reason all the intermolecular forces which bind together the molecules of solids and liquids would be so small that we might safely prophesy that it would be a gas of very low boiling point. All these properties are exhibited by the elements helium, neon, argon, etc., which form the group of inert gases. We may therefore say with some certainty that the elements constituting this group are those in which all the electrons are fixed.

The elements which immediately follow them in the list form what is known as the alkali group and are placed in the first group of the periodic classification of the elements (see page 111). By our hypothesis they contain one more electron than the elements of the argon group which immediately precede them in the list. They have thus one free or valency electron. Moreover, as the system is only just stable the attraction of the central nucleus for this single valency electron may be expected to be very small. It will thus readily part with it under the action of slight external forces, leaving the atom itself positively charged. The element will thus be strongly electropositive in character, and a good conductor of electricity. These are, in fact, the characteristic properties of alkali metals in Group I.

Similarly the elements contained in Group II, immediately succeeding these, will have two valency electrons, those in Group III three, and so on. In

other words the number of free or valency electrons increases uniformly from one to seven as we pass from Group I to Group VII of the periodic classification. Thus sodium has one, magnesium two, aluminium three, sulphur six, and chlorine seven of these mobile electrons. Direct experimental confirmation of these results is afforded by experiments on the dispersion of light. We have already mentioned that the dispersion of light is due to these

TABLE VII—NUMBER OF FREE ELECTRONS IN THE ATOM DEDUCED FROM THE DISPERSION OF LIGHT

Substance	Calculated number of dispersive electrons	Number deduced on theory of grouping
Hydrogen	1.4	1
Calcium	1.5	2
Carbon	3.7	4
Silicon	3.9	4
Oxygen	4.4	6
Chlorine	6.2	7

mobile or valency electrons, and by some rather abstruse and approximate calculations Drude has succeeded in deducing entirely from optical considerations the number of these electrons contained in the atoms of some of the different elements. His results are contained in Table VII. Remembering that the number of electrons must in any case be a whole number, and that the calculations are somewhat approximate in nature, his calculated values would seem to fully bear out the results to which we have been led by our theory of atomic structure.

On the other hand, the force with which these electrons are retained in the atom increases with the charge on the central nucleus. The two free elec-

trons in the magnesium atom, for example, will be more firmly attached than the single one in the sodium atom, while those in the atom of aluminium will be still less easily detached. The elements will thus become less and less electro-positive, and, on the whole, worse conductors of electricity as we pass along a series from Group I towards Group VII. Further, we have seen that in general an atom may not only lose electrons, it may also acquire them, if circumstances are 'avourable. Now the chlorine atom, with its seven uncombined electrons, needs only one electron to make its electron system completely stable. On general principles we may easily see that, other conditions being the same, it is much more likely to stabilise itself by attracting an additional electron into its system than by the diastic process of parting with seven. The chlorine atom, in other words, would have a strong attraction for the electrons in neighbouring atoms, tending to become itself negatively charged. Thus chlorine should behave as a strongly electro-negative element, as in fact it does. Thus we should expect the elements immediately preceding one of the inert gases to be strongly electro-negative, while those immediately following them in the list would be equally strongly electro-positive, the character of the elements gradually changing from the one to the other as we pass along from Group I to Group VII. A glance at the periodic table of the elements (page 111) will show that this is precisely what occurs.

The position of the metals in Group VIII of the Periodic table is somewhat anomalous. While the properties of the preceding elements suggest that the electron grouping is tending towards complete stability at these points, the elements themselves exhibit a rather complex set of positive valencies, showing that they certainly contain mobile electrons. The properties of the elements immediately succeed-

ing them in Group I are also different, as might be expected, from those of the members of that group which follow the inert gases. The facts suggest that at the  $s$  points the more usual rings of eight electrons give place, or tend to give place, to one of perhaps sixteen, but it must frankly be confessed that our present knowledge of the actual groupings of the electrons in the case of these more complex atoms is not sufficient to make our speculations on the point of much value. The same may be said of the case of the series of what are known as the metals of the rare earths, which, with atomic weights which differ but little from each other, and chemical properties which differ less, have not yet been definitely fitted into the periodic scheme. In this case it is also possible that differences in the structure of the positive nucleus may not be without some influence.

One further point may be referred to in this connection. It can be shown that when two atoms of different sizes come into contact, the attraction of the smaller atom for the electrons contained in the larger exceeds that of the larger atom for the electrons in the smaller. There is thus a resultant force tending to drive electrons from the larger to the smaller atom. Thus, even among atoms of the same type, those with a smaller volume will tend to acquire, those with a larger volume will tend to lose, electrons. In the same group, therefore, the elements of greater atomic volume will therefore be more electro-positive (or less electro-negative, as the case may be) than the elements with the smaller atomic volume. Now in any one group of elements the atomic volume increases with increasing atomic weight. Hence we arrive at the general result that the electro-positiveness of the elements in any one group increases with increasing atomic weight. This relation has often been pointed out. A very striking example of it is seen in Group V of the periodic classification, where

the lightest element, nitrogen, is usually electro-negative, while the heaviest, bismuth, is almost invariably electro-positive

Thus in spite of some gaps, the accuracy with which our deductions from the theory of atomic structure to which our experiments have led us reproduce at any rate the grand outlines of the periodic classification of the elements is, indeed, most remarkable. This great generalisation, no longer tantalising and inscrutable, is seen to be the direct result of the laws of electron grouping which we have arrived at from our study of the constitution of the atom. While it is much to be regretted that the failure of mathematical analysis to keep pace with the outburst of experimental activity does not permit us in most cases to apply numerical tests, the accuracy with which our theory reproduces the main outlines of this great generalisation of descriptive chemistry affords us considerable hope that eventually we shall be able to explain all the manifold physical and chemical properties of matter in terms of the electrical forces exerted between the positive and negative particles, which, on our view, constitute the atom.

## CHAPTER VII

### THE ELECTRON THEORY OF VALENCY

THERE is one property of the chemical elements which we have not yet considered, though it is perhaps the most important, namely, their power of combining together to form molecules of compound substances. Of chemical affinity, that elusive and mysterious force, our theory of atomic structure must give some adequate explanation, as, after all, there is no property of an element more characteristic than its power to form compounds with other elements. Ever since the time of Berzelius the view has been held, more or less tenaciously, that the forces binding together the different atoms within the molecule were electrical in their origin, that, for example, the molecule  $\text{NaCl}$  of sodium chloride was formed by the mutual attraction of a positively charged sodium atom for a negatively charged atom of chlorine. This view was, of course, based on the phenomena of electrolysis. When an electric current is passed through a solution of sodium chloride in water it is found that the sodium makes its way to the negative electrode, the chlorine to the positive. The salt thus behaves as if the sodium atoms bore a positive and the chlorine a negative charge. It is an obvious assumption that the atoms in the molecule of sodium chloride bear the same charges as they are actually found to possess when in an aqueous solution, and that the electrical attraction between these equal and opposite charges is the bond which unites the two atoms together in the compound molecule.

In the case we have been considering both the elements are monovalent, and it can be shown from the laws of electrolysis that they carry equal and opposite charges. From a consideration of the electrolysis of such compounds as magnesium chloride,  $MgCl_2$ , in which a divalent atom is combined with two monovalent atoms, it is easy to show that the charge on a divalent atom is twice that carried by the atom of a monovalent element, and that in general there is a direct proportionality between the ionic charge and the chemical valency. This result is a logical and necessary result of the laws of electrolysis.

So long, however, as the ionic charge was regarded as something apart and distinct from the atom itself, something of a different nature super-added to it by mysterious external agency, the electrical theory—except in so far as it explained the phenomena of electrolysis in which it had its use—was no more fundamental and distinctly less workable than the chemical theory of bonds of affinity. As we shall see later, it is possible to assign a real physical significance to the idea of a bond of affinity.

With the electron theory of matter the situation is quite changed. The electric charge is no mere addendum to the atom. It is a vital part of its structure, and the question whether a given atom will tend to lose or gain electrons, and, if so, how many, will depend entirely on the number and arrangement of the electrons within it and the forces with which they are retained.

To return to the case of sodium and chlorine. We saw at the end of the previous chapter that sodium contains a single mobile or valency electron as we have called it, with which it will readily part under the action of external forces. Chlorine, as we observed, had seven such, but owing to the fact that this number is very close to that required to form a

stable ring system, we deduced that chlorine would in general be much more likely to absorb the one electron necessary to achieve this result, and would thus tend to acquire a single negative charge.

Thus, when sodium and chlorine are brought together—the former with a strong tendency to lose an electron, the latter with an equally strong tendency to gain one—it is evident that the mobile electron will pass from the sodium atom to the chlorine, leaving the former with a unit positive charge, and giving the latter a unit negative charge. It may be noted in passing that we have shown in an earlier chapter that the charge carried by a monovalent ion in electrolysis is exactly equal to the charge on an electron. The attraction between these two charges will then be the force which binds the two together in chemical union. As the sodium has now lost its only free electron, while the chlorine atom has acquired the one needed to complete a stable ring system, it is obvious from what we have said of the principles of electron grouping that no further action can take place. The compound is completely saturated.

To come now to the case of magnesium chloride. Magnesium, having, as we have seen, one more electron than sodium, has two mobile, or valency electrons as we have called them, which it can give up under suitable circumstances. But a single chlorine atom can only absorb one. Hence two chlorine atoms are required to denude the atom of magnesium of its stock of mobile electrons, and the compound molecule will consist of one atom of magnesium and two of chlorine, the magnesium having two unit positive charges, and each of the chlorine atoms a single negative charge, in other words, the magnesium atom is electro-positive and divalent. Similarly aluminium with three valency electrons will be trivalent, and so on. The positive valency

of an element is therefore equal to the number of valency electrons which it contains

Now we have seen that the number of valency electrons is fixed by the position of the element in the Periodic classification, the number increasing uniformly from one in Group I to seven in Group VII. Thus we should expect that the positive valency of the elements would increase uniformly from one in Group I to seven in Group VII. This is found to be the case, though owing to their extremely electro-negative character the positive valencies of the elements in the latter group are very infrequently exerted.

To pass now to the negative valencies, we have already seen that the negative valency is determined by the number of electrons which the atom can absorb. In the case of chlorine this is unity, and chlorine is thus a monovalent electro-negative element. Sulphur, immediately preceding it in the table and therefore containing one electron fewer, will require, and can absorb, two electrons to make up a stable ring. It will therefore have a negative valency of two, in other words, the negative valency of the elements will increase from unity to seven as we pass backwards along a series from Group VII to Group I.

Each element therefore on our scheme of atomic structure will possess two valencies—the one positive and equal to the number of valency electrons which it contains, and the other negative and equal to the number of electrons which it requires to make up, together with those which it already possesses—a fixed electronic system. Thus, phosphorus with five valency electrons would have a positive valency of five, as, for example, in the compound  $\text{PCl}_5$ , or a negative valency of three, as in the case of  $\text{PH}_3$ . Which of these valencies will be exerted will depend largely on the nature of the atom with which it is

brought in contact. In general, however, we should expect that the forces acting would tend to make the number of electrons in the atom equal to that stable number to which it was nearest to begin with. Thus elements possessing fewer than four valency electrons would be electro-positive, those with more than four electro-negative, the elements of Group IV with four valency electrons being indifferently positive or negative. Our complete theoretical scheme of valency is thus represented by Table VIII, where the Roman

TABLE VIII—TABLE OF VALENCIES OF THE PERIODIC GROUPS

Group	I	II	III	IV	V	VI	VII
Normal valency	+ 1	+ 2	+ 3	$\pm 4$	- 3	- 2	- 1
Additional or contra-valency	- 7	- 6	- 5		+ 5	+ 6	+ 7

numerals indicate the group in the Periodic classification. It is most interesting to note that Professor Abegg in an illuminating paper on valency arrived at a precisely similar scheme from a careful study of the chemical compounds of the elements. He suggested that every element had two valencies—a normal and a contra-valency—the normal being supposed to be the stronger. The positive valencies were normal for elements of Groups I to III, the negative for Groups V to VII, Group IV being indifferently positive or negative. In every case the sum of the two valencies was found to be eight. It will be seen that these observations of Professor Abegg are exactly embodied in our theoretical table.

The phenomena of unsaturated compounds present no difficulties. It is not necessary, or indeed

to be expected, that the whole of the available electrons should be extracted from the atom in a single stage. It is evident that the work done in extracting the second electron will be greater than that for the first, and it is easy to imagine cases in which the attraction of the combining atom might be sufficient to produce the expulsion of one but not of two electrons. Since, however, the atom of higher valency would still contain some displaceable electrons, it would still exert an appreciable force on atoms in its neighbourhood, which, under suitable circumstances, would lead to the addition of further atoms to the molecule. The compound would thus be unsaturated.

The theory of valency, which we have now described at some length, gives such a successful and adequate explanation of the main facts of valency that there can be no doubt that in the main we have been proceeding along right lines, and that in many cases we have arrived at a very close approximation to the facts. The interchange of an electron between, say, the atom of sodium and that of chlorine in the case of sodium chloride is proved by the charges which these atoms are found to bear when the compound is dissolved. The resultant electrical attraction between the charged atoms is an adequate explanation of the bond of affinity which links them together to form a compound molecule of salt. In other cases, however, the theory in its simple form presents obvious difficulties. Take as a very simple instance the molecule  $H_2$  of hydrogen gas. The system, consisting as it does of two hydrogen atoms, is a very stable one, requiring a very high temperature for its dissociation. The bond between the two atoms in the molecule of hydrogen is stronger than that between the atoms in the molecules of many compounds. It is impossible to suppose that the bond in this case is radically different from that between

the atoms, say, in a molecule of carbon monoxide. On the other hand, since the two hydrogen atoms are exactly similar, it is equally impossible to suppose that there can be any tendency for an electron to pass from one to the other.

Light has again been thrown upon the subject by the researches of Sir J. J. Thompson. His work on the positive particles in the discharge tube, which we have described in a previous chapter, has led him to recognise the existence of two great classes of molecules, namely those in which the individual atoms are charged as we have assumed on the previous theory, and a second class in which the individual atoms are uncharged. If we suppose, for example, that the atoms in the molecule of carbon monoxide are charged, the carbon positively and the oxygen negatively, we should expect that when the compound was broken down by the stresses in the tube they would retain these charges, just as in the case of an electrolyte in solution to which we have already referred. We should expect, therefore, that there would be an excess of negatively charged oxygen atoms and an excess of positively charged carbon atoms in the resulting stream of particles. As a matter of fact this is not the case. We must conclude therefore that the atom leaves the molecule in an uncharged condition, and is thus presumably uncharged when in the molecule itself. On the other hand, the evidence of the positive ray tube is equally clear that in some cases, such as that of water vapour or ammonia gas, the individual atoms do carry a charge away with them when the partnership is dissolved, and are therefore presumably in a charged state in the molecule.

We are thus led to divide chemical compounds into two great classes: those in which the forces between the atoms have not been sufficient to bring about the passage of an electron from the one to the

other, and those in which such an exchange has taken place. Molecules of the second class may conveniently be termed "*ionised*," and the process may be spoken of as *intra-molecular ionisation*. In the former class we should naturally place molecules such as  $H_2$ ,  $O_2$ ,  $CO$ ,  $NO$ , etc., the constituent atoms of which do not differ very widely in their electrochemical character, to the second or ionised class we should assign compounds of the more violently opposed elements, such as  $H_2O$ ,  $HCl$ ,  $NH_3$ , together with the whole class of electrolytes. These results are borne out by the experiments with the discharge tube.

We should also expect to be able to differentiate between the two classes of compounds by their physical properties. We have seen that the inter-molecular forces which give rise to the phenomena of cohesion, rigidity, surface tension and the like are due to the action of the charged systems in the atoms and molecules. Now the force exerted by a system of charges depends not only upon the magnitude of the charges, but also on the distance by which they are separated, the strength of an electrical doublet, for example, being measured, like the moment of a magnet, by the product of the strength of either of the charges into the distance between them. Now it is evident that this distance will be greater when the poles of the doublet are situated on different atoms than when both the charges are confined within the same atom. The electrical field will therefore be abnormally large in molecules which are ionised, and the physical characters which depend on this field will be especially well developed. Compounds in which this intra-molecular ionisation occurs should thus be characterised by high surface tension and large latent heats, if liquid, and by great tenacity and rigidity if solid.

A still more valuable criterion is furnished by the

specific inductive capacity of the compound. We have seen that, electrically speaking, we may regard the positive charges on the nucleus and its surrounding electrons as forming a set of electrical doublets. Now, if an electric potential difference is applied to the substance, the electrical doublets will tend to set themselves in such a way that their fields will be opposed, and will thus tend to diminish the applied field, in exactly the same way that a number of small magnets set themselves in a magnetic field. The result of this will be that the strength of the field produced by a given electric charge will be appreciably less than it would have been in the absence of any material substance. This phenomenon is known as specific electric induction. Now the greater the strength of these doublets the greater the effect, and hence the greater the specific inductive capacity. Thus compounds in which the charges are attached to separate atoms will be characterised by a high specific inductive capacity.

Again, before the external potential difference is applied, the doublets will be arranged indifferently with their axes in every direction. They are turned into line by the action of the external field itself. Now there will be a great difference in the time taken by the two kinds of compounds to adjust themselves to the external field. The valency electrons, as we have seen, are very light and very mobile. We know from optical phenomena that their natural frequency is comparable with that of ultra-violet light. They will therefore have no difficulty in adjusting themselves to variations in the external field even when they are as rapid as those which occur in the light waves of the visible spectrum.

On the other hand, if the two charges of the doublet are situated on different atoms, the setting of the doublet will necessitate the rotation of the

whole massive molecule—obviously a much slower process. Now in the case of ordinary electrical experiments, where the field is usually applied to the substance in the same direction for at least an appreciable fraction of a second, there will be ample time for these heavy doublets to adjust themselves to the field, and they will thus add their full value to the specific inductive capacity of the substance. In the case of such very rapid oscillations of the field as are known to occur in waves of light this adjustment will obviously be impossible, and the specific inductive capacity as deduced from optical experiments will be much less than that obtained from electrical experiments of the usual kind.

Now, Maxwell has shown that on the electromagnetic theory of light there is a simple relation between  $K$ , the specific inductive capacity of a substance, and  $n$ , its refractive index, which may be expressed by the equation  $K = n^2$ . It is well known that in many cases the value of  $K$  deduced from this expression is identical with that obtained by direct electrical measurement, but that in others the relation does not hold even approximately. For example in the case of water, electrical measurements of the specific inductive capacity give a value of about 79, while that deduced from its refractive index by Maxwell's law is only 1.78. This discrepancy between experiment and theory has always been felt to be distinctly unsatisfactory, and science is indebted to Sir J. J. Thomson for this simple, adequate, and elegant explanation. It is an interesting confirmation of the theory that these discrepancies are always to be found in the case of compounds in which we know from independent evidence that the atoms are charged.

We may therefore use the law of Maxwell as a means of determining to which of our two great classes of compounds any given substance belongs. If Maxwell's law holds, as in the case of hydrogen,

oxygen, nitrogen, carbon monoxide, carbon dioxide, and nitrous oxide, to mention only a few, the atoms in the molecule are uncharged. If, on the other hand, Maxwell's law does not hold, as is the case for water, the alcohols, ammonia, hydrochloric acid, etc., the compounds belong to the second class, and have intra-molecular ionisation. It is obvious that the recognition of these facts will have important bearings in many directions. At present, however, we are only concerned with their application to the subject of valency and the nature of chemical affinity.

We have already seen that an atom, being a system of negative and positive charges, will exert an electric field which extends for some appreciable distance beyond the boundaries of the atom, these forces giving rise to the phenomena of cohesion, rigidity, surface tension, and so on. Now consider a molecule made up of two atoms. The atoms will attract each other, on account of these electrical forces, they will also be attracted by other atoms and molecules in their neighbourhood. If their attraction for each other is greater than the attraction of the surrounding atoms and molecules, it is evident that they will remain attached to each other, that is to say the molecule will be stable. If, however, the attraction of the external atoms and molecules is comparable with the mutual attraction between the two atoms, their union will be dissolved and the molecule will be unstable. From this point of view chemical affinity differs from cohesion and the other molecular forces not in kind but merely in intensity. We may say, then, that from an electrical standpoint a given molecule will be stable if its component atoms do not exert on neighbouring atoms or molecules attractions comparable with those between the individual atoms in the molecule itself. We have now to consider how this condition can be satisfied.

Let us return to the case of a simple doublet,

such as we have supposed the hydrogen atom to be. Since one pole is positive and the other negative, the forces exerted at the two ends of the axis will be opposite in character. The immediate force exerted by one atom upon another will thus depend on the orientation of the two when brought together, just as one magnet will either attract or repel another according as we bring opposite or similar poles into contact. As the atoms will come into contact in all sorts of ways the force will on the average be as often repulsive as attractive. If, however, the systems are free to move, they will, by the ordinary laws of mechanics, always arrange themselves so as to attract each other, but this will require a time the length of which will depend on the rapidity with which the doublets can move. Now the valency elections are characterised by their great mobility, and will thus adjust themselves very rapidly to fresh conditions. In the case of the fixed electrons in the ring systems the adjustment will require the rotation of the comparatively heavy atomic system. This would necessitate a greater force and a more prolonged connection between the two atoms for its completion. It is therefore unlikely to occur, as the atoms, even in the solid state, are in comparatively rapid motion.

It follows, therefore, that an atom in which all the electrons are fixed will in general be unable to exert any great force on the atoms around it. From an electrical point of view, therefore, a molecule made up of such atoms would be stable, or, in chemical terms, it would be saturated. Our new criterion of saturation is, therefore, simply this, that all the elections in the atom shall be held fixed by the forces acting upon them. Since only the valency electrons are free to move, the number of electrons requiring to be fixed to ensure saturation is obviously equal to the number of valency electrons which the atom contains.

It remains to be seen now how the electrons can be fixed. It is evident, in the first place, that this can be effected by the passage of the requisite number of electrons from the one atom to the other. Thus when an electron passes from the atom of sodium to that of chlorine, the sodium atom is left without any mobile electrons, while the addition of the single electron to the seven already present in the chlorine atom fixes them automatically by enabling them to form a stable system. Thus in the case of molecules possessing intra-molecular ionisation, the valency conditions which satisfy the earlier theory will also automatically satisfy the conditions of the new. For such compounds, therefore, no fresh hypothesis is required. The case of the molecules in which the individual atoms are uncharged, however, requires further consideration. The simplest way is to consider the question from the point of view of the Faraday tubes of electric force, which have thrown so much light on electrical phenomena in general.

Let us suppose that a single tube of force commences on each electron and ends on some positive charge. If the tube of force starting on a valency electron terminates on the nucleus of the same atom it will leave the electron free to rotate about the nucleus, and thus at liberty to move about within the atom. If, however, the tube of force is anchored to something outside the atom, say to the nucleus of another atom, the electron will be fixed by the tension in the tube, and its mobility will be thus destroyed. Thus if a given atom contains, say, four valency electrons, it will be completely saturated when each of them is linked by its tube of force to the nucleus of some other atom. This condition cannot require more than four other atoms to satisfy it as two or more of the tubes may go to the same atom it may require less. The element will thus have a maximum positive valency of four. That is to

say, the positive valency of an atom will be equal to the number of valency electrons which it contains, exactly as in the case of the ionised compounds

On the other hand, since the atom is neutral as a whole in the compounds which we are now considering, a tube of force must enter it from without for each tube which leaves it. This is necessary in order to neutralise the positive charge which will be set free by the transference of the attraction of the electron from its own nucleus to that of some other atom. The bond between the atoms is thus a double one, consisting of one inwardly and one outwardly directed tube of force. To take a concrete case, two atoms of hydrogen will attract each other because each contains a mobile electron, and the two systems will therefore be able to adjust themselves so as to make the force between them one of attraction. If, however, the free electron in each atom transfers its tube of force to the nucleus of the other, both will be rendered immobile, and the molecule will be saturated. The union can be represented by the symbol  $\text{H} \rightleftarrows \text{H}$ , where the arrows indicate the direction of the tubes of force. It will be seen that this connection is perfectly symmetrical, the two atoms functioning, as we should expect, in exactly the same way. The theory thus accounts for the undoubted fact that precisely similar atoms do exhibit for each other a very marked chemical attraction.

On the other hand, the new view opens the way to the possibility of valency compounds, which would be quite impossible on the older and more orthodox ideas of valency. It is not necessary, as far as we can see at present, that the tubes of force which enter and leave a given atom should connect it to the same atom. Thus, a molecule such as  $\text{H}_4$  would be a possible valency compound on this theory, being represented by the diagram in Fig. 22. This particular allotropic form of hydrogen has

been detected by Sir J J Thomson among the particles in his positive ray tubes. In general, as far as the present theory goes, a closed ring of any number of atoms of the same valency would satisfy the conditions laid down, and thus form a possible valency compound, providing that all the atoms were uncharged. It may be noticed that in the case of the elements there seems to be a tendency to form molecules, which, especially in the solid state, contain a considerable number of atoms, and it is very likely that such molecules have the ring structure which we have suggested. In the case of compounds, however, such an arrangement is certainly very rare,

FIG 22 —STRUCTURAL FORMULA OF  $H_2$

and there must be other factors which make such a ring compound unstable in the majority of cases. The theory needs here some little restriction, the nature of which will perhaps become obvious when the actual arrangement of the electrons in the atom is better understood. The difficulty only arises in the case of compounds in which the individual atoms are uncharged. In the case of compounds possessing intra-molecular ionisation the conditions of the newer theory lead, as we have seen, to exactly the same results as those of the original hypothesis.

The theory has the advantage of allowing us to assign symmetrical formulæ not only to the molecules of diatomic elements, but also to the much-discussed benzene ring. It may be remembered that while the ordinary structural formulæ for benzene

exhibit a certain want of symmetry, the properties of the substance itself afford no evidence of any distinction between the various carbon atoms in the ring. The simplest formula for benzene on the new theory is represented by the diagram on Fig 23. It will be seen that the linkages between the carbon atoms in the ring are exactly the same for each, while it differs, as we should expect, from the ethane, ethylene and acetylene linkages. The theory has

FIG 23—STRUCTURAL FORMULA OF BENZENE.

evidently important applications in the study of organic chemistry

So far we have only been considering the valency due to the existence in the atom of mobile or valency electrons—that is to say, the positive valency—and as we have seen in the case of hydrogen, and in the much more complicated case of benzene, there is no reason, on the newer view, why a molecule should not be formed from atoms all of which are exercising their positive valencies. It is no longer necessary that the atoms should differ electro-chemically for them to unite. On the other hand, it is certainly

the fact that an atom like that of chlorine, which contains a large number of valency electrons, behaves in its most characteristic reactions as a monovalent negative element. In the majority of cases in which the negative valency is exercised—for example, in the case of the metallic chlorides—the compound possesses intra-molecular ionisation, and is formed with the interchange of an electron. In this case, as we have already pointed out, the new and the older theories become identical, and no difficulty arises. Negative valencies are, however, undoubtedly exercised in compounds such as  $\text{C Cl}_2$ , which shows no signs of intra-molecular ionisation. The passage of an electron is therefore not essential to the existence of negative valency.

Assuming that a ring of eight electrons is automatically stable, Sir J. J. Thomson suggests that we may perhaps regard a cluster of seven electrons, like the valency electrons of chlorine, as being equivalent to a ring of eight together with a single positive charge. The ring of eight will be self-saturated, while the positive charge would require only a single inwardly directed tube of force to fix it. The atom would thus exercise a single negative valency, or alternately a positive valency of seven. It would obviously not be able to exercise both these valencies simultaneously. While this supposition satisfies the chemical and electrical requirements, it must be confessed that it is a little difficult to visualise in our present state of knowledge as to the constitution of the atom, and seems more of the nature of a statement of the problem than a solution of it.

On the other hand, the existence of unsaturated compounds presents no great difficulty. Thus, for example, in the case of carbon monoxide, which we may represent by the formula  $\text{C}\equiv\text{O}$ , the oxygen atom is saturated but the carbon atom is not

On the other hand, although the oxygen atom is saturated and all its electrons fixed it will still exert a field of force in its neighbourhood. In the case of other atoms outside its own molecule this field will, as we have seen, on the average be as often repulsive as attractive, since it will depend on their orientation at the moment of approach. The carbon atom is, however, actually linked to the oxygen atom, and thus, as far as the carbon atom is concerned, the field of force of the latter will be constant and always in the same direction. The mobility of the two remaining valency electrons will obviously be impaired by the action of this residual field, and the attraction of the carbon atom for other atoms will thus be decreased. The question as to whether the decrease will be sufficient to allow the compound to exist in a free state will depend on the strength of the residual field. Thus, in the case of carbon monoxide the residual field of the oxygen atom is sufficient to render the compound stable. In the corresponding case of  $\text{C}_2\text{H}_2$ , which does not exist under ordinary circumstances (it has been identified in the positive ray tube) the residual field of the two hydrogen atoms is insufficient to prevent the union of two neighbouring molecules to form  $\text{C}_2\text{H}_4$ .

Every electronic theory of valency must be of a tentative nature until the question of the actual magnitude of the forces exerted by the atomic systems has yielded to mathematical analysis. There seems no immediate probability of this. In the meantime the hypotheses which we have been discussing certainly afford a reasonable explanation of the main outlines of the problem of chemical affinity, and may be expected to throw much light on some of the more complicated cases of chemical action.

## CHAPTER VIII

### THE ATOM IN VIBRATION

It can easily be shown that when a moving electric charge is accelerated or retarded in any way, a wave of electro-magnetic disturbance radiates out through the surrounding space. Consider an electron with its Faraday tubes moving along in the direction AB (Fig 24). If the electron is moving with uniform

FIG 24—PRODUCTION OF ELECTRO MAGNETIC DISTURBANCES  
BY THE STOPPAGE OF AN ELECTRON

velocity these tubes will travel along with the electron as if they were rigidly attached to it. Suppose, however, that this electron on reaching a point C is suddenly stopped in its career. The ends of the Faraday tubes attached to the electron are suddenly brought to rest.

Now a Faraday tube is in some respects very like a stretched rope. For instance, it has a tension

along its length, and possesses, as we have seen in a previous chapter, mass. Thus, just as when one end of a rope is jerked, a certain definite time elapses before the displacement reaches the other end, so a displacement in a Faraday tube does not reach all points of it simultaneously, but is propagated along it with a definite velocity. In the case of the stretched rope the velocity is equal to  $\sqrt{\frac{T}{m}}$ , where

$T$  is the tension on the rope and  $m$  its mass per unit length. On similar principles it can be shown that the velocity of a disturbance along a Faraday tube is equal to  $\frac{1}{\sqrt{\mu K}}$ , where  $\mu$  is the magnetic per-

meability and  $K$  the specific inductive capacity of the medium through which the disturbance is travelling. We will call this velocity  $V$ .

Now, during the time it has taken for the jerk to travel from the electron  $O$  to a point  $P$ , the portion of the tube beyond  $P$ , not having received the signal that the electron has been stopped, has been travelling on with its original velocity and is now in the position  $P'$ , where  $PP'$  is the distance which the electron would have gone in the time taken for the disturbance to travel along the tube from  $O$  to  $P$ . Thus a kink is developed in the tube which travels outward along it with the velocity  $V$ .

The bent portion of the tube  $PP'$  is moving perpendicular to its length and will thus, by the principles we have already developed, produce a magnetic field in the medium, which will also travel out with the kink. If we consider all the tubes surrounding the particle, it will be seen that these bent portions will form a kind of sheet of disturbance travelling outwards as an expanding spherical shell or wave.

If we can determine for any medium the values

of  $\mu$  and  $K$  in the same system of units, we can calculate the velocity  $V$  with which the disturbance is propagated in that medium. It will be remembered that the electrostatic system of units was obtained by defining  $K$  the specific inductive capacity of air as unity. The electro-magnetic system, on the other hand, assigns this value to  $\mu$  the magnetic permeability of air. The comparison of the two systems can best be performed by measuring the capacity of the same condenser according to both systems of units. This operation is described in most text-books of electricity, and its details are outside the scope of our present work. The results obtained are, however, most striking and important. The result of a long series of experiments at the American Bureau of Standards extending over several years has given a value for  $V$  of  $2.997 \times 10^{10}$  cm per second. This is, within the limits of experimental error, identical with the best determinations of the velocity of light, which have given a mean value of  $2.998 \times 10^{10}$  cm per second. The agreement between the values obtained for the two velocities is too close to be accidental. It affords a convincing proof of the electro-magnetic nature of light.

In the case we have considered where the particle is suddenly brought to rest a single pulse is formed the thickness of which is equal to the distance through which the disturbance can travel in the time taken to stop the particle. Such pulses are given out when cathode rays in a discharge tube impinge on a solid anticathode. They give rise to the well-known phenomena of Röntgen or X-rays.

If, instead of stopping the particle dead, we cause it to oscillate about a mean position, a series of undulations will be set up in the Faraday tubes attached to it, such, for example, as are seen when one end of a long rope is shaken regularly to and fro. Thus

a series of electro-magnetic waves move out from the vibrating electron, their frequency being equal to the number of vibrations made by the particle per second. Their wave length is equal to the distance travelled by the disturbance during the time of one complete vibration. If this lies between 0.0004 and 0.0008 mm these waves will produce on our eyes the impression of light. This, in its crudest form, is the Faraday-Maxwell electro-magnetic theory of light.

Not only may light originate in the vibration of electrons, all our experiments drive us to the conclusion that such vibration is the only way in which light can be produced. Uncharged matter is apparently quite incapable of setting up any kind of disturbance in the æther. It is the electric charge which serves as the only link between the two.

We can, however, proceed further than this. Modern research has enabled us to identify with certainty the vibrating systems which emit the myriad lines in the spectra of the elements with the electrons, with the properties of which we are now growing familiar.

Michael Faraday, with almost uncanny prescience, seems to have felt that the relation between magnetism and light must be of the closest, and sought for it with unremitting diligence. It is one of the little ironies of life that the only effect which he did discover (the magnetic rotation of the plane of polarisation) was one of the very few phenomena which theory even now is hardly adequate to explain. The effect he sought for was not discovered until, more than thirty years later, his experiments were repeated with stronger magnetic fields and far more powerful methods of spectrum analysis by Zeeman.

He found that if a source of light was placed between the poles of a strong electro-magnet and the light emitted was examined spectroscopically, a

curious change took place in the appearance of the different lines in the spectrum, each being split up or decomposed into two components when the light was viewed along the lines of force in the magnetic field, or three when viewed at right angles to this direction

Let us consider briefly the effect of applying a magnetic field to the charged particles emitting the vibrations as they oscillate about their mean positions. In general the path described by a particle will be somewhat complicated. We can, however, resolve its motion in the usual way into vibrations

FIG 25 — ILLUSTRATING THE DECOMPOSITION OF A HARMONIC MOTION INTO TWO CIRCULAR VIBRATIONS

parallel to and at right angles to the lines of force in the magnetic field

The vibrations performed along the lines of the field will be unaltered by the application of the field since the latter produces no mechanical effect on a particle moving in its own direction. It will be quite different with those vibrations which are executed in directions at right angles to this. It is shown in works on mechanics that any harmonic vibration can be regarded as the sum of two circular motions of properly chosen amplitude and phase. For example, the harmonic motion of a particle A vibrating along the straight line BC (Fig 25) is exactly equivalent to the motions of two equal

particles P and Q describing the circles shown in the diagram with equal velocities, but in opposite directions

It will be sufficient, therefore, and will lead to no loss of generality, if we consider the charged particles as describing circles at right angles to the magnetic field, under the action of forces directed towards the centre of the circles. Since the motion of the charged particles is now everywhere at right angles to the magnetic field there will be a mechanical force acting on the particles which will be everywhere at right angles to the magnetic field, and to the direction of motion of the particles. A little consideration will show that it must always act in the line joining the position of the particle at any moment to the centre of the circle.

Particles such as P and Q are, however, describing their circles in opposite directions. Thus the magnetic force will be in one case directed towards, in the other away from the centre of the circle. In the first case the total force dragging the particle towards the centre is increased, the circle is contracted and the time of vibration becomes more rapid. In the latter the effective force is diminished, with the result that the orbit expands and the vibrations become slower.

An apple whirling round at the end of a string will furnish a very useful analogy. If the tension of the string is increased the apple is drawn in and its revolutions become more rapid. If, on the other hand, the tension is relaxed, the apple takes a wider sweep, while the time it takes to complete a single revolution becomes longer.

Thus, instead of all the particles describing their orbits in exactly the same time and thus producing light of one frequency only, one set have been accelerated, the other retarded by the magnetic field, so that instead of a single line the spectroscope

will reveal two, one on each side of the original position of the line. By optical means we can distinguish between clockwise and counter clockwise rotations, and can thus determine which of the two has been accelerated and which retarded by the magnetic field. Since the effect on a positive particle would be exactly the reverse of that on a negative, we can thus determine the sign of the charge carried by the vibrating particle. In every

FIG. 26.—ILLUSTRATING THE ZEEMAN EFFECT. N, S ARE POLES OF ELECTRO-MAGNET. A, B REPRESENT THE APPEARANCE OF A SINGLE LINE EMITTED BY THE FLAME AS SEEN THROUGH A SPECTROSCOPE PLACED IN THE TWO POSITIONS.

case so far examined it has been found to be negative.

If we view the flame along the lines of force, these two new lines are the only ones seen, as the vibrations taking place in the line of sight produce no effect on the eye. If, however, we look across the field, the vibrations executed along the lines of the field will also produce their effect in the spectroscope, and since their period is unaltered by the field they will give a line in the position of the original undecomposed line. Since all the circular

paths are being now viewed end on, all three lines will appear to be plane polarised. These results are shown diagrammatically in Fig 26

This in its simplest form is exactly the effect discovered by Zeeman in 1896. He found that if a source emitting a line spectrum were placed between the poles of a very powerful electro-magnet and viewed with an interference spectrometer of

FIG 27 —, THE ZEEMAN EFFECT (a) UNDECOMPOSED LINE (b) SAME LINE VIEWED ALONG THE LINES OF FORCE OF A MAGNETIC FIELD (c) LINE VIEWED AT RIGHT ANGLES TO LINES OF FORCE

high resolving power, the line was seen to be split up into three components when viewed at right angles to the magnetic field and into two when seen along the lines through a hole in the pole piece. This is very well shown in the photograph reproduced in Fig 27. When, at the suggestion of Lorentz, who at once saw the correct explanation, the polarisation of the different components was

examined, it was found to agree exactly with that described above

We have seen that these observations have shown that the vibrating system is negatively charged. We can, however, go further than this. Following up the argument given above it can easily be shown\* that if  $\lambda_s$  and  $\lambda_c$  are the wave lengths of the two outer components into which a single line of wave length  $\lambda_0$  is split up

$$e/m = \frac{\lambda_c - \lambda_s}{H \lambda_0^2} 2 \pi V$$

where  $e/m$  is the ratio of the charge to the mass for the particles and  $V$  is the velocity of light\*. Now Runge and Paschen found that for a certain series

of mercury lines, for example, the value of  $\frac{\lambda_c - \lambda_s}{\lambda_0^2}$

was 2.14 for a magnetic field of 24,600 units, while  $V$  is, of course,  $3 \times 10^{10}$  cms per second. Substituting these values in the equation we have

$$e/m = \frac{2.14 \times 2 \pi \times 3 \times 10^{10}}{24,600} \text{ or } 1.65 \times 10^7$$

Considering that the displacement produced by even the strongest fields amounts generally to somewhere about one-fifth of the distance separating the two D lines of sodium, it will be seen that this result agrees even better than might have been expected with the value of the same ratio  $1.77 \times 10^7$  deduced for the negative electron from experiments on cathode rays. The identity of the light-emitting systems with the cathode ray particles must be regarded as established beyond all challenge.

Many spectral lines show the Zeeman effect in this simple form. Others, however, give more complicated effects, some of the lines of Molybdenum,

\* See Appendix C

for example, splitting up into seventeen and even nineteen components. We have, in assuming that the vibrating electron executed harmonic vibrations, neglected the possibility of its motion being disturbed by the forces due to neighbouring electrons in the same atom. If these are not negligible complications ensue, and the time of vibration is no longer independent of the direction in which it takes place. The matter has been discussed at length for certain simple systems of electrons by Professor Sir J. J. Thomson, and his paper may be found in the *Proceedings* of the Cambridge Philosophical Society, Vol. 39, by any who are interested in pursuing the matter more deeply.

The lines in the spectra of an element thus represent the different modes of vibration of the electrons connected with it. It might seem that with a complete knowledge of these periods at our disposal it should be possible to reconstruct the atom with certainty. Theoretically, no doubt, this should be so. The mathematical difficulties are, however, appalling, and only in the case of a few very simple systems is the analysis at all possible. Thus the results to be looked for from spectroscopy are at present qualitative rather than quantitative.

Even so, however, a study of spectra is most luminously suggestive. A careful analysis of the innumerable lines which are dotted apparently at random through the spectra of the elements has shown that they are by no means the confused jumble of periods which at first sight they appear to be. It has been found that in very many cases they can be grouped into definite series, every line of which can be obtained by substituting particular whole numbers for a variable quantity " $m$ " in a general equation the form of which is the same for all elements.

This was first pointed out by Balmer for the

hydrogen spectrum, but it was afterwards shown by Rydberg that Balmer's equation was merely a particular case of a very general law which could be stated so as to apply to all the elements giving series spectra. He showed that if  $n$  is the frequency of the vibrations corresponding to a given line (the frequency is the number of vibrations made per second by the particle emitting the light), then the frequency of all the lines in a given series can be represented by the equation—

$$n = n_{\infty} - \frac{N}{(m + \mu)^2},$$

the different lines composing the series being obtained by putting  $m$  equal successively to the whole numbers, 1, 2, 3, while  $N$  is a constant so universal in its character that it applies not merely to all the series of a given element but to all the series of all elements giving series of spectra at all. The constants  $n_{\infty}$  and  $\mu$  differ for different elements and are characteristic of the particular series.

That this method of classifying a spectrum is no mere mathematical fiction is very clearly brought out when the character of the lines making up a single series is closely observed. It is found that all the lines of a single series are exactly similar in appearance. Thus all of them appear sharp and distinct with definite clear-cut boundaries, or else they are all indistinct and diffuse. The two types of lines are never associated in the same series. Again, any physical change which we bring about in one of the lines of a series is reproduced simultaneously in all the others. Thus, all the lines split up in the same way under the action of a magnetic field. If one of the lines is broadened by the application of pressure to the gas emitting the spectrum, all the others are broadened to a similar degree, and when the method of producing

the spectrum is altered, all the lines have their brightness either enhanced or diminished at the same time. We can hardly avoid the conclusion that they are all different modes of vibration of the same system.

An analogy may make this clearer. It is well known that when an organ pipe is sounded it gives out in addition to its fundamental note a series of overtones, the fulness and richness of the organ notes being due to the presence of these extra tones. In such a simple system the overtones are always harmonics, that is to say, their frequencies are always exact multiples of the lowest mode of vibration. In mathematical language we can say that the different frequencies are obtainable by substituting various whole numbers for the quantity  $m$  in the equation,  $\lambda = m \lambda_0$ .

In more complicated vibrators the relationship becomes more complicated while at the same time the importance of the overtones becomes even more pronounced. In the case of a sounding bell the relation between the different modes of vibration is so complicated that it has not yet been completely worked out.

This is not all, however. Not only do the spectra of a single element show these close numerical relationships. They are also found to exist between the spectra of different elements belonging to the same group of the periodic table. The spectra of the different elements of the alkali metals, for example, are so closely connected that it is actually possible to calculate the whole spectrum of, say, rubidium or caesium, from that of potassium, and a knowledge of the relative atomic weights of the three elements. The spectrum of caesium is practically the same as that of potassium but is shifted bodily towards the violet end of the spectrum. We are thus driven to the conclusion that the

vibrating systems in the two cases are identical in form, and differ from each other only in being placed in slightly different environments

In terms of our model atom, if we regard the series spectra as being given out by the inner rings of electrons, these rings are identical for the three elements, but in the case of the two latter the extra outer rings added on to increase the atomic weight produce some alteration in the external forces acting on the rings and so cause a shift in the absolute frequencies of the vibrations without altering the relation between them. In the words of astronomical theory, the outer electrons perturb the vibrations of the inner ring without destroying their character. Or, returning to our analogy of the bell, it is the same bell which is sounding but in a somewhat different medium.

One difficulty, a very formidable one, remains, and may, perhaps, already have occurred to the reader. The spectra of many of the elements is exceedingly complicated, containing in some cases many hundreds of well-defined lines. A contemplation of the hydrogen spectrum wrung from the great American spectroscopist Rowland the exclamation that, compared with an atom of iron, a grand piano must be a very simple affair indeed.

We have seen, however, in a former chapter that the number of electrons in an atom is, on the whole, not very large. In all probability the hydrogen atom contains only one electron. A single electron has only three degrees of freedom and therefore only three modes of vibration, and in the simple atom even these three would all have the same period and thus coalesce into a single line. As a matter of fact, the ordinary spectrum of hydrogen contains a fair number of lines, while what is known as its secondary spectrum is very complicated. The difficulty seems at first sight almost insuperable.

To solve the riddle, Professor Sir J. J. Thomson has hazarded the bold but almost certainly correct conjecture that the lines in the spectrum of hydrogen and, indeed, of many other elements are not emitted by the atoms of the element at all, but by systems which only exist when the gas is thrown into a luminous condition. When we consider the absolute identity of the spectrum of an element whether situated on the earth or away on the furthest star of which we have spectroscopic data, this hypothesis may seem to be the most startling we have yet advanced. It is, however, not without a very considerable experimental basis.

Consider for a moment the phenomenon known as the selective absorption of light, of which the well-known experiment of the reversal of the sodium lines is a good example. If white light is passed through sodium vapour enclosed in an iron tube and the transmitted light examined with a spectroscope there can be seen across the ordinary coloured spectrum two sharp, dark lines, corresponding exactly in position with the two bright lines, which would be seen if the sodium were raised to incandescence. This is the cause of the dark Fraunhofer lines which are to be seen crossing the spectrum of the light from the sun.

These effects are due to a form of resonance. The sodium atom contains systems of electrons which, when suitably excited, give out light of the frequency corresponding to the two sodium lines. To use an analogy from sound or from wireless telegraphy the sodium atom is tuned to this frequency. It will therefore begin to vibrate violently if oscillations of this period fall upon it. In doing so it abstracts the energy of the radiation in tune with itself, so that the latter is very rapidly absorbed, while light of frequency remote from this passes on almost unaffected. Thus, after passing through a

very small thickness of material the light is robbed of all the constituents which have frequencies corresponding to those of the radiating systems within it. Conversely all the electronic systems which have natural periods falling within the limits of the visible spectrum must produce a dark band when white light is passed through them.

Now, it is remarkable that such absorption lines

FIG 28—LADENBURG'S EXPERIMENT

The inset shows the appearance seen in spectrometer when the tubes are working *aa*, broadened band due to hydrogen in A *bb* spectrum due to the tube B alone. The dark line where the two bands cross shows the reversal of the line by the systems formed in B by the discharge.

are not seen when white light is passed through a column of hydrogen, or indeed of most other simple gases. There are, for example, no dark lines to be seen in the spectrum of light which has passed through a long tube of hydrogen gas, corresponding to, say, the brilliant lines of the hydrogen spectrum in the red or in the blue. Indeed, the laws of the absorption and dispersion of light in hydrogen are so simple that they can be explained on the assumption

of a single absorption band far away beyond the violet end of the spectrum. This is, of course, what we should expect from the simple nature of the hydrogen atom. There is thus no escape from the conclusion that the vibrating systems which emit the hydrogen spectrum are not present in the gas in its normal condition.

A very interesting experiment made not long ago by Ladenburg has shown, however, that they can be manufactured in the gas under suitable conditions. He passed the light from a very bright discharge in hydrogen at fairly high pressure through a long tube of hydrogen at much lower pressure, fitted with terminals for the passage of a discharge, and examined the light transmitted with a spectroscope. His apparatus is indicated very diagrammatically in Fig. 28. The effect of the high pressure on the discharge is to widen out all the lines in the spectrum so that, instead of a narrow line, a broad band of light is seen overlapping the original line on each side. When there was no discharge passing through the long tube of hydrogen there was no trace of any absorption of any part of this broadened band.

If, however, a feeble discharge was sent through this long tube of gas it was seen that the centre portion of the broad line corresponding to the original line and hence having the period of the light emitted by the tube at low pressure became distinctly less bright than the outer portions, showing that the long column of feebly glowing gas was now absorbing from the light emitted by the brighter hydrogen tube those wave-lengths corresponding in period to the light it was itself giving out. There are some difficulties in the experiment, and a certain synchronism of the two discharges seems to be necessary for its success. On the whole, the conclusion seems irresistible. The hydrogen line spectrum is emitted by systems of electrons which are not present in the

gas in its normal condition, but which are formed when the gas is thrown into a luminous state

Let us consider for a moment the ways in which an atom can be made to emit luminous vibrations. Experiments have shown that for an atom to emit its characteristic spectrum it is necessary that it should be in a region of intense ionisation or recombination. It seems that nothing short of driving an electron into or out of the atom will suffice to set in vibration the light-emitting systems of electrons. It is obvious that this condition is fulfilled when the spectrum is excited electrically, either by sparking between terminals of the substance or by a low pressure discharge through a gas. It is interesting in this connection to note in the latter case that experiments have shown that, in the dark portions of the discharge the ionisation is very feeble, while it is most intense in the brightest portions of the positive column. The ordinary method of producing a spectrum by placing the substance in a Bunsen flame is also merely a rough-and-ready way of producing ionisation in the substance, Professor H. A. Wilson having shown that a Bunsen flame, especially if it contains salt vapours, is the seat of very intense ionisation.

Consider an atom placed within this ionised space. It meets the ionising agent and an electron is ejected, leaving the atom with a positive charge. The loss of this electron will alter the forces within the atom and the remaining electrons will oscillate about their new positions of equilibrium before finally settling down. These vibrations, if of suitable periods, will set up luminous radiations and give rise to a set of lines in the spectrum. The positively charged atom is now surrounded by a cloud of negative electrons which fill the surrounding space. It attracts them and, normally, one would enter to take the place of the lost member. If, however, the

mutual kinetic energy of the two is sufficient, the electron will revolve round the attracting atom without falling into it in exactly the same way as the earth revolves around the sun. The revolutions of this electron, being isochronous, will give rise to a single line in the spectrum with a period equal to the time taken by the electron to describe the circle.

If the law of force between the atom and the electron were the simple one of the inverse squares, an orbit of any size would be possible under suitable conditions. Taking into account the fact that the electron is losing speed owing to the fact that it is all the time radiating away its energy in the form of light-waves, it will be gradually drawn nearer and nearer the atom so that its path would be a sort of spiral ending up in collapse into the atom. Since slightly different times would be occupied in describing each part of the curve the spectrum thus produced would be continuous.

The neighbourhood of the electrons within the atom and their repulsion of the external one would complicate the simple law of force, and in general the attraction of the atom for its satellite would depend not only on the distance but also on the direction of the line joining the satellite to the atom. The actual law of force would thus depend upon the number and arrangement of the electrons within the atom, just as much as if the electron were revolving inside it.

Sir George Darwin, in his monumental work on Periodic Orbits, has shown that, if the single system of a satellite revolving round its planet is disturbed by the presence of a third body, the number of orbits which the satellite may describe is no longer infinite, but that there are certain regions through which the particle must not pass if it is to continue to revolve as a satellite around the planet. In the simple case considered by Darwin this space

did not quite enclose the planet, but in more complicated cases such as we have to deal with when we come to a consideration of the atom, he was of the opinion that it might very well take the form of a series of closed rings surrounding the atom. In this case there would be a series of separate rings in which alone the electron could revolve, and each of which it would describe in a definite time peculiar to that ring. Each of these rings would thus give rise to a separate line in the spectrum. Since the atom would only attract one electron at a time each atom would at one time be only emitting one of these extra lines.

These systems would, of course, not be permanent, as the electron would constantly be losing energy by radiation. After a time its energy would fall below that necessary to keep it in rotation in the ring it was describing, and it would collapse through ring after ring, until finally it was reabsorbed into the atom. Fresh systems would, however, be constantly being formed in the ionised gas, and the supply would be kept up as long as the exciting conditions were maintained.

The return of the lost electron into the atomic fold would obviously stir up fresh vibrations among the electrons already present. Since the atom is now neutral and not positively charged as it was when the electron left it these vibrations would not have the same periods as those set up when the electron was expelled. There is some evidence for the suggestion that the vibrations corresponding to the return of the electron form the band spectrum of the element, while those set up on its expulsion, together with those due to the special systems, make up the different series of line spectra.

Very recently an ingenious Danish mathematician, Dr Bohr, has worked out mathematically a theory of spectra very much on the lines described

above, and has in this way obtained a formula for the spectral series identical in form with the empirical formula of Rydberg which we have already discussed. He has from his theory deduced an expression for the universal constant  $N$  of Rydberg's equation in terms of the mass and charge on an electron and other known physical quantities, which gives a numerical value for that quantity within about 5% of the value obtained from direct spectroscopic observations. His assumptions will require further consideration before they can be unreservedly adopted. They appear to involve the abandonment not merely of Newtonian mechanics, but also of the ordinary Faraday-Maxwell electro-magnetic theory. The closeness of the agreement between the results of the theory and of experiment is, however, at least remarkable, and seems to show that, at any rate in its general outlines, the theory of the origin of spectra which we have propounded above is a step in the right direction.

We have, however, wandered far from the solid certainties of the Zeeman effect and its consequences, with which we commenced this chapter, into the dark and mysterious hinterland where science is in the making. In a few more years we may hope that this will be transformed into plain and open ground. At present we must pause here, lest we lose ourselves altogether in a quagmire of fascinating but groundless speculations.

## CHAPTER IX

### THE MOLECULAR THEORY OF MATTER

WE have now surveyed very briefly what is known and surmised of the nature and properties of the atom and molecule. In the brief space of the present chapter let us indicate one or two of the many points of interest which arise when we come to consider the molecule, not as standing by itself, but as massed together in myriads to form a fragment of what we know as matter.

In solids, we must regard the molecules as fixed relatively to each other, and we have in an earlier chapter considered briefly the nature of the molecular forces, cohesion, adhesion and the like, which bring about this result. But though the molecules are fixed, in the sense that they are not free to move about in the solid, we cannot consider them as being altogether motionless. Every body, unless it is at the absolute zero of temperature (a temperature which has not yet been reached in any experiment, although the brilliant researches of Kamerlingh Onnes have brought us within  $4^{\circ}$  of it), contains a certain definite amount of heat. Now heat is merely energy in a molecular form. The work which we do in raising the temperature of a substance is in reality spent in increasing the energy of the individual molecules of the substance, and thus in every body which is not at the absolute zero, the molecules must be in some sort of motion,

the rapidity of which increases as the temperature is raised

The molecules of the solid are not free to move from their positions, but two forms of motion are possible to them. They may either spin round like a top, or oscillate backwards and forwards about their mean position, like the bob of a pendulum, or like a heavy weight suspended by an elastic cord.

In the case where the molecule is a system made up of two or more atoms, both these kinds of motion take place. The atoms spin round their common centre, at a rate which increases as the body gets hotter, while at the same time the molecule as a whole oscillates backwards and forwards about its mean position with ever-increasing amplitude. If, however, the molecule consists of a single atom, only the latter form of motion seems to be possible, all the evidence going to show that thermal energy is unable to set a single atom spinning about its own centre.

For the sake of simplicity we will consider the case of the mon-atomic molecule, where the thermal energy is all used in the second kind of motion. As the body gets hotter and hotter, the molecule moves faster and faster, and the swings which it takes on each side of its normal position get larger and larger. The molecular forces which keep it in position, however, fall off very rapidly as the distance between the neighbouring molecules is increased, while at the same time the force required to retain the molecule in position increases with every increase in velocity. Hence, sooner or later, a point is reached when the molecular forces are no longer able to retain the atoms in position. The solid loses its cohesion and its rigidity. In other words it melts.

It is obvious that melting sets in when the tem-

perature is just sufficient to give the molecules the necessary minimum of velocity to overcome the molecular forces retaining them in position—that is to say, it will be a constant for any definite substance. Also as work must be done to break down these inter-molecular bonds it is evident that energy must be supplied to the body in the form of heat to enable it to melt. This is the latent heat of liquefaction.

Though the molecule has broken its old bonds, it is still within the range of molecular attraction of many of its neighbours, and has hardly escaped from one cluster before it is attracted into another. Its rate of progress is thus comparatively slow. In time, however, any given group of molecules will be found dispersed throughout the whole of the liquid and thus diffusion is brought about.

Consider now the state of affairs at the surface of the liquid. Every molecule as we know attracts every other molecule which may happen to be within a certain distance from it which we denote as the sphere of molecular attraction. In the body of the liquid, this attractive force is more or less neutralised by the fact that the molecule we are considering is surrounded on all sides by others, all pulling in different directions. Hence the combined effect is practically zero. At the surface, however, all the molecules are below it, and there are none above to neutralise the force which they exert. There is thus a strong downward force tending to drag the molecule into the surface. This force makes itself manifest in the phenomenon known as surface tension or capillarity.

A molecule will thus require a definite and in most cases a considerable velocity to succeed in escaping from the surface of the liquid. Now the mean velocity of the molecules depends only on the temperature, and is fixed for any given sub-

stance when the temperature is known. The actual velocity of any given molecule at a given instant may, however, differ very considerably from this average speed. The molecules in the liquid are constantly bumping against each other, and at every collision one of the molecules will probably gain speed, and the other lose it, and a difference in velocity is thus set up. The law of the distribution of speeds among an infinite number of colliding molecules has been worked out by Maxwell, for the simpler case of a gas, and is known as Maxwell's law. He showed that at any given instant the great majority of the molecules would have velocities not widely removed from the average, but that there would always be a few which, owing to special circumstances, would have velocities very much greater, and others with velocities very much less, than the normal value.

Thus for oxygen at  $0^{\circ}\text{C}$ , in which the mean velocity of the molecules is 425 metres per second, out of every 1,000 molecules of the gas, about half have velocities between 300 and 500 metres per second, but there are 77 with a velocity greater than 700 metres per second, and 30 with a velocity greater than 900 metres per second.

The case of a liquid is much more complicated than that of a gas, but there is no doubt that a similar state of affairs prevails in the liquid state also. Hence, even at temperatures far below the boiling point of the liquid, there will be a few molecules which have temporarily sufficient speed to escape from the attraction of the mass of liquid below them.

Thus, even at low temperatures, a certain number of molecules escape every second from the free surface of the liquid. If the space above the liquid is free there will thus be a constant evaporation going on until all the liquid disappears into vapour.

If, however, the liquid is contained in a closed vessel, the escaping molecules are unable to get away altogether, and after perhaps many reflections at the enclosing walls will sooner or later strike the surface of the liquid and be reabsorbed. The number so returned to the liquid will depend on the number of molecules present in the vaporous state above the liquid. Evaporation will go on until the number of molecules in unit volume of the vapour is so great that the number returned per second is exactly equal to the number which escape per second owing to their high velocity. Thus for every temperature there will be a corresponding vapour pressure which will be constant for that temperature and that pressure. If the temperature is raised, the average speed of the molecules is increased, and more of them will attain a velocity sufficient to enable them to escape from the surface. The vapour pressure thus rises. When the vapour pressure reaches that of the atmosphere the liquid will begin to boil, and if the supply of heat is maintained, will all pass into the state of a gas.

The difference between a liquid and a gas is that in the latter all the molecules are moving with sufficient speed to escape completely from the attraction of their neighbours, and are thus able to avoid those molecular aggregations which take place in the liquid state. On this account the behaviour of a molecule in a gas lends itself much more readily to mathematical analysis than the more complicated phenomena of the liquid and solid states. The kinetic theory of gases has been very completely worked out by Maxwell, Clausius, and their successors. Unfortunately, even with the simplifications thus introduced, the theory needs considerable mathematical ability for its elucidation, and does not lend itself at all readily to non-mathematical treatment.

The pressure which a gas exerts on its boundaries is made up of the innumerable shocks given to the bounding walls by the many impacts upon them of the molecules of the gas, which are moving as we have seen with considerable speeds. It will obviously depend on the number of molecules present per unit volume, and the speed with which they are moving. The higher the temperature, the faster the molecules move, and the greater, therefore, will be the pressure they exert. It can be shown that this pressure is simply proportional to the temperature, if we begin to measure the latter not from the freezing point of water, but from the absolute zero of temperature, that is, the temperature at which the molecules would all be reduced to rest. This temperature is about  $273^{\circ}$  below the zero on the Centigrade scale.

Again, if we halve the volume occupied by the gas, we double the number of molecules present in every cubic centimetre, and hence double the pressure which they exert on the enclosing walls. The pressure is thus inversely proportional to the volume occupied by the gas and directly proportional to its absolute temperature, thus, if  $P$  is the pressure,  $V$  the volume and  $T$  the temperature, of a given mass of substance in the gaseous form,  $P/V/T$  is a constant. This is the well-known gas equation embodying the laws of Boyle and Charles.

These laws are obeyed approximately by all gases, but perfectly by none. We have assumed in calculating the formula that the molecules exert no attraction upon each other in the gaseous state. This is of course only approximately true. Hence the velocity with which the molecules strike the boundary is always a little smaller than the normal velocity at that temperature, owing to the attraction of the molecules behind it. This effect will obviously be greater if the molecules are closely packed together.

than if they occupy a large volume. It has been shown that to get the true pressure we must add to the observed pressure an amount equal to  $a/V^2$ , where  $a$  is constant for a given gas.

Again the actual space in which the molecules are free to move is less than the whole space of the vessel, owing to the fact that the molecules are not mere mathematical points, but have a definite volume of their own. Thus if  $b$  is the whole volume occupied by all the molecules in a gas, the actual free space in which they are free to move is not  $V$  the volume of the vessel, but  $V - b$ .

To be accurate, therefore, we should write our gas equation in the form—

$$\left(p + \frac{a}{V^2}\right) (V - b) = RT,$$

where  $R$  is a constant for the gas.

This equation was first given by Van der Waals, and is found to represent the behaviour of real gases with a considerable degree of accuracy. In fact it is even capable of representing with some degree of success the transition state from liquid to gas. It has the further advantage, that it offers us a simple method for determining the one molecular dimension with which we are still unacquainted, namely, the radius of the molecule.

By accurate experiments on the behaviour of the gas under varying conditions, we can determine the value of the constant  $b$  in any given case. Since one molecule cannot pass between two others if the space between them is less than the diameter of a molecule, the volume  $b$  occupied by the molecules in the gas will be somewhat greater than the sum of their individual volumes. If  $r$  is the radius of each molecule, and  $N$  the total number of molecules present in the gas, a number which we have already determined, it can be shown that—

$$b = \frac{4}{3} (\frac{4}{3} \pi r^3) N,$$

assuming that the molecules are spheres. In compound gases where there are several atoms in the molecule this can hardly be the case, but in the case of mon-atomic gases where the atom is also the molecule, it seems a probable assumption. Hence knowing  $N$ , we can calculate the value of  $r$  the radius of the molecule of the gas we are considering. A few of the values so obtained are given in Table IX. It will be seen that they are of the order of  $10^{-8}$  or one hundred millionth of a centimetre. The radius of an electron is  $10^{-13}$  cms, or about one ten thousandth part of this. The size of

TABLE IX  
THE RADIUS OF THE MOLECULE

Substance	From Van der Waals equation	From the viscosity	From the thermal conductivity
Hydrogen	$1.16 \times 10^{-8}$ cm	$1.23 \times 10^{-8}$ cm	$1.20 \times 10^{-8}$ cm
Helium	1.15 "	1.09 "	—
Nitrogen	1.76 "	1.75 "	1.66 "
Oxygen	—	1.70 "	1.55 "
Argon	1.43 "	1.68 "	—
Carbon dioxide	1.70 "	2.09 "	2.16 "

an electron thus bears to the size of the molecule in which it moves very much the same relationship that the diameter of our earth bears to the diameter of its orbit round the sun. A molecule is therefore a system very similar in its relative dimensions to the solar system but on an infinitesimal scale.

The kinetic theory affords other methods of estimating the dimensions of a molecule, but their theory is too complicated to be attempted in the space that remains. The results obtained are in-

cluded for the sake of comparison in Table IX. The second column of figures gives the value of the radius deduced from considerations of the viscosity of the gas, the last column the value deduced from its thermal conductivity. The three values agree among themselves as well as could be expected.

Let us return now for a brief space to our solid again. Solids may be divided into two classes, according as they do or do not conduct electricity. It is also found that conductors of electricity are also good conductors of heat, while electrical insulators are generally very poor conductors of heat. We have by now come to connect electricity with electrons, and hence an electric current is a flow of electrons from a place of high to a place of low potential. We may regard a conductor, then, as a substance containing electrons which are free to move under the action of an electric field, while in non-conductors the electrons are fixed and unable to follow the impulse of the field.

How are these electrons set free? In the first place it may be noticed that the only good conductors of electricity are metallic, that is to say, electro-positive in character, substances which we know from other phenomena readily part with an electron under the slightest provocation. Now in a solid such provocation may well be supplied by the close propinquity of the neighbouring molecules. It is well known that a charged body will attract light uncharged substances. The attraction of a well-rubbed stick of sealing-wax for small pieces of paper is generally our first introduction to the science of electricity. The attraction is, of course, mutual, the force on the charged body being equal to that on the uncharged paper. Hence an electron in one atom is attracted by a neighbouring uncharged atom, and under favourable circumstances, and especially in the case of an atom only too ready to

part with its electrons, the attraction may well be sufficient to enable it to make its escape

That some such assistance is necessary and is so given is shown by the fact that a metallic vapour is no better a conductor than any other gas at the same temperature. Thus while metallic mercury at its boiling point is an excellent conductor of electricity, the mercury vapour above it conducts little better than the air it displaces—that is, practically not at all.

The evolution of electrons by the molecules of a metal is very similar to the evaporation of a liquid into a closed space—a phenomenon we have already described. It will go on until the number of electrons which are attracted by the positively charged residues and so recombine, is equal to the number of electrons which are given off by the neutral molecules in the same time. Thus for a given temperature there will be a definite pressure of electrons per unit volume in the metal, and we may in fact look upon the electrons as a kind of tenuous gas filling up the interspaces between the molecules of the solid. We must regard them as moving about in all directions in the solid with considerable velocities. The principles of thermodynamics would lead us to imagine that when equilibrium is established each of these electrons will have the same average energy as the molecules around it—that is to say, the energy corresponding to the temperature of the body at the time. This is an important point to which we shall return later.

These electrons, if no electric force be acting, will be moving in all directions, so that if we take any cross section of the metal the number of electrons crossing it in one direction will be the same as the number crossing in the opposite direction, and so the total transference of electricity across the section will be zero.

If, however, we apply an electric field to the body there will be a force on each electron urging it in the direction of the field. Thus in addition to the irregular motion due to the heat energy of the body, there will be a steady drift of the electrons as a whole in the direction of the electric force.

Let us consider for the sake of simplicity a regular conductor such as a uniform wire. Let us apply an electric field  $X$  to the wire along its length. Then the force on every electron is equal to  $Xe$ , where  $e$  is the charge on an electron, and it can be shown that the average velocity  $v$  of the electron due to the electric field is  $KXe$ , where  $K$  is some constant which for the moment we will leave undetermined.

In one second all the electrons which are less than  $v$  cms from a given cross section of the conductor will be forced across it under the action of the field. The volume of this space is  $vA$  if  $A$  is the area of cross section, and thus if there are  $N$  electrons per unit volume, each carrying a charge  $e$  the total charge passing through the given cross section will be  $NevA$  units per second. But this is by definition the current along the conductor. Hence remembering that the velocity  $v$  is  $KXe$  we have the current  $i$  is equal to  $K e^2 N A X$ .

If  $d$  is the length of the wire and  $E$  the difference of potential between its ends, the field  $X$  in the wire is equal to  $E/d$ . Hence finally

$$i = (K e^2 N) \frac{A}{d} E$$

The current through a given conductor is thus directly proportional to the difference of potential between its ends which is the well-known law of Ohm. We see that it is also proportional to the cross section of the conductor, and inversely proportional to its length. We may thus write it—

$$i = \sigma (A/d) E,$$

where  $\sigma$  is written for the quantity in the bracket. This is a well-known expression for the current through a wire. The quantity  $\sigma$  which is a constant for a given substance at a given temperature, is known as its specific electrical conductivity. Comparing the equations we see that the conductivity  $\sigma$  is equal to  $K e^2 N$ .

Now the constant  $K$  can be evaluated on certain probable assumptions and has been shown to be equal to  $V \lambda / 6 R T$ , where  $V$  is the velocity of the turbulent motion of the electrons,  $\lambda$  is the average distance traversed by the electron between one collision with a molecule and the next,  $R$  is the well-known constant from the gas equation, and  $T$  is the temperature of the conductor on the absolute scale. Hence finally the electrical conductivity of a substance is given by the expression

$$\frac{N e^2 \lambda V}{6 R T}$$

This relation contains several quantities which are at present unknown to us, and so we cannot put it directly to the test. Let us proceed, however, a little further.

Suppose now that instead of applying an electric field to the metal, we begin to heat one end of it. We have seen that the turbulent velocity of the electrons depends only on the temperature, and hence the electrons in contact with the heated area will begin to move with a greater speed than those in the colder parts of the substance. These electrons are moving in all directions, and so in course of time, some will move away into the colder regions, carrying their increased velocity with them. Their places near the hot end will of course be taken by electrons from the colder parts, which in turn will have their motion accelerated by contact with the hot face.

Thus there will be a constant stream of quickly moving electrons from the hot end into the cold parts of the body, sharing their energy with, and thus increasing the velocity of, the molecules there. But the temperature at any point in the body depends only on the speed with which the particles are moving. Thus to translate the process from molecular to molar physics, heat has been conducted from the hot to the cold parts of the body, and the rate at which this process takes place measures what is called the thermal conductivity of the substance.

Since then the free electrons play the principal rôle both in the conduction of electricity and the conduction of heat, we should expect to find some sort of relation between the conductivity of a substance for heat and its conductivity for electricity.

It has long been known that good conductors of the one are also good conductors of the other, and as long ago as the middle of last century, Wiedemann and Franz, by comparing the experimental results for a number of metals, discovered that the ratio of the thermal to the electrical conductivity had the same value for all metallic elements. Somewhat later Lorentz, by making the comparison at different temperatures, found that the magnitude of this ratio was simply proportional to the temperature at which the comparison was made, reckoned from the absolute zero of temperature. These results are well brought out in Table X. The second column gives the ratio of the thermal to the electrical conductivities at 18° C for the metals given in the first column of the table. The last column gives the observed temperature coefficient of the ratio. If Lorentz' law is true, this coefficient should have the value 0.0366.

For many years this empirical law of Wiedemann and Franz remained without explanation. The

electron theory of conduction would, however, as we have seen, lead us to expect with confidence some such relationship. We can, however, go further than this. We have already seen how to calculate the electrical conductivity of a metal. Its thermal conductivity can also be calculated if we assume that the heat is all carried by electrons. This assumption cannot be strictly true, because substances which are non-conductors of electricity still conduct heat to a small but finite degree. In this case the transference of heat is carried on by the molecules themselves, the

TABLE X

Metal	Ratio of thermal to electrical conductivity	Temperature coefficient of the ratio
Copper	$6.71 \times 10^{10}$	0039
Silver	$6.86 \times 10^{10}$	0037
Gold	$7.09 \times 10^{10}$	0037
Nickel	$6.99 \times 10^{10}$	0039
Zinc	$6.72 \times 10^{10}$	0038
Cadmium	$7.06 \times 10^{10}$	0037
Lead	$7.15 \times 10^{10}$	0040
Iron	$7.35 \times 10^{10}$	0034
Platinum	$7.53 \times 10^{10}$	0046

heated molecules transferring their increased velocity to their immediate neighbours by the somewhat tedious process of repeatedly bumping against them. This method is necessarily slow compared to that of the freely moving electrons, and the very small thermal conductivities possessed by electrical insulators leads us confidently to suppose that the amount of heat transmitted in this way in a metal conductor is very small compared with that carried by the electrons.

The free electrons in a metal behave, as we have seen, like a rarefied gas. We can therefore apply the

results obtained for gases to them. The thermal conductivity of a gas has been worked out by Maxwell and others. The mathematical analysis of the problem would lead us too far. It is contained in all treatises on the dynamical theory of gases. It is found that the thermal conductivity of a gas is represented by

$$\frac{1}{2} N \lambda V R$$

where  $N$ ,  $\lambda$ ,  $V$ , and  $R$  have the same meaning as in the equation for electrical conductivity.

Hence comparing the two equations we have—

$$\frac{\text{Thermal conductivity}}{\text{Electrical conductivity}} = \frac{1}{2} (N \lambda V R) - \frac{N e^2 \lambda V}{6 \pi R T} \\ = 3 \frac{R^2}{e^2} T$$

This is a very simple relation indeed. All the quantities with which we are unfamiliar have gone out, leaving only  $R$  the constant of the gas equation,  $e$  the ubiquitous electronic charge, and  $T$  the temperature on the absolute scale at which our comparison is made. Let us substitute for these symbols their numerical values, and so bring our theory to a critical numerical test.  $R$  in absolute units is equal to  $1.40 \times 10^{-16}$ , while  $e$  in electro-magnetic units is  $1.57 \times 10^{-20}$ . If the comparison is made at  $18^\circ \text{C}$ , as in Table X,  $T$  is  $(18^\circ + 273^\circ)$  or  $291^\circ$  on the absolute scale.

Hence, the ratio of the two conductivities should be equal to—

$$3 \times \frac{(1.40 \times 10^{-16})^2}{(1.57 \times 10^{-20})^2} \times 291, \\ \text{or} \quad 6.95 \times 10^{10}$$

The agreement with the experimental values given in Table X is satisfactory beyond the bounds of expectation. Since  $R$  and  $e$  are both independent of the temperature, it is evident from our equation

that the ratio varies directly as the absolute temperature, as was discovered experimentally by Lorentz

The electron theory of conduction has many other triumphs and at present also not a few unsolved difficulties, which would need a treatise rather than a chapter to expound. Let us, therefore, leave the subject here, and take a final and farewell glance at our atom, this time in the throes of dissolution

## CHAPTER X

### THE ATOM IN DISSOLUTION

If the ideas which have been developed in the preceding chapters have any sort of foundation in fact, the title of the present chapter will hardly come as a shock to any reader. It may seem at first sight much more surprising that a system, so complex as the one we have described, and in such constant motion, when subjected to all the shocks mechanical, chemical, and electrical, which an atom must undergo, should continue to exist in such a persistent and unchangeable way as is actually found to be the case.

The cause is probably to be found in the relatively enormous amount of energy associated with an atom, an amount which is quite out of proportion to the energy liberated by chemical reactions. It has been shown that the heat liberated by the transformation of one gram of radium into its final products is about  $4 \times 10^9$  gram calories, or roughly speaking it is equal to the heat generated by the combustion of half a ton of coal. Compared with this enormous quantity the heat liberated in the most energetic of chemical reactions fades into insignificance. The formation of a gram of water, for example, is attended by the emission of about  $4 \times 10^3$  gram calories. And yet this enormous quantity must only be a small fraction of the total energy in the radium atom. Radium, as we shall see, has an atomic weight of 226.5, the final product

of its decomposition one of about 206. This atom, whatever it may be (modern speculation points to lead, but the proof is not complete), is stable, and must possess a very large amount of energy of its own. The total energy in an atom must therefore be enormous, and it is for this reason that all efforts to transmute one element into another have failed.

The main outlines of the new science of radio-activity are perhaps familiar to all readers. The subject is one of profound interest, but it lies almost wholly outside the scope of such a work as this. We will, however, summarise such of the main facts of that science as bear on our immediate subject, leaving the proof of the various statements and the description of the often very beautiful experiments from which they were deduced to other hands.

The metal uranium and its compounds were found by Becquerel to give off continuously particles capable of affecting a photographic plate at a considerable distance. These are the  $\beta$ -rays which, as was mentioned in an earlier chapter, are identical except in speed with the cathode rays.

If the uranium salt is subjected to certain chemical processes it is possible to separate the uranium compound into two fractions. In one fraction, an almost imperceptible part of the whole, all the power of emitting  $\beta$ -rays is concentrated. The other, containing practically all the original salt, is completely inactive. For example, if we follow Sir William Crookes and shake up crystals of uranium nitrate in ether, the water of crystallisation, which settles out beneath the ethereal solution and can be separated from it by a separating funnel, is found to contain by far the greater part of the  $\beta$ -ray activity of the whole, the great mass of the salt now dissolved in the ether being comparatively inactive.

Let us take these two solutions and keep them

under observation for some time. It will be noticed that the watery solution is gradually losing its  $\beta$ -ray producing powers, the rate of emission of these rays falling in fact to half its original value in about twenty-five days. At the same time the ethereal solution which we had rendered inactive gradually

FIG 29—GROWTH AND DECAY OF  $\beta$ -RAY ACTIVITY WITH TIME FOR URANIUM AND URANIUM X

begins to radiate again, so that at the end of twenty-five days it has recovered one-half of its original activity. Fig 29 shows in a graphic way the exact correlation between the loss of radio-activity by the active fraction and the growth of activity in the inactive mass. It will be seen that the total activity

is constant throughout the experiment. From these results we may draw the following conclusions:

- In the first place, the property of ejecting these electrons with enormous speeds resides not in the uranium itself, but in some substance which is mixed with it but which can be separated from it by suitable chemical processes.
- Secondly, this substance is not a stable substance but loses its activity with time.
- Lastly, this substance is not of the nature of an impurity in the uranium, but is so vitally bound up with it that when the latter is completely freed from its presence it can reproduce this strange substance again at a steady and perfectly definite rate.
- The conclusion seems irresistible. Some new substance is being produced out of uranium itself, and in turn is decomposing with considerable celerity into some other substance which for the moment we are unable to pursue.

I have discussed the case of uranium because that metal is a recognised element belonging to a well-known and respectable family, and might have been expected to behave in a rational and orthodox manner. The case of radium (which is actually a decomposition product of uranium) is still more striking. Rutherford discovered that radium and its salts are constantly giving off a heavy, chemically inert gas known as the "emanation," a non-committal name bestowed upon it before its nature had been determined. This emanation collects in the radium, but can be extracted from it by heating under reduced pressure, or better still, by dissolving the salt in water and boiling the solution. In either way the radium can be completely freed from this new gas. On allowing the gas and the radium to stand, however, it is found that fresh emanation makes its appearance in the radium, while the collected emanation gradually disappears, the relation between the growth and decay of the emanation

being precisely similar to that of uranium and its  $\beta$ -ray producing product. It is impossible to escape the conclusion that the element radium is evolving out of its own substance the heavy gas known as the emanation.

TABLE XI

Element		Average life	Rays emitted
(Uranium) <sub>1</sub>	238 5	$5 \times 10^9$ years	$\alpha$
Uranium X <sub>1</sub>	(234 5)	24 6 days	none
Uranium X <sub>2</sub>	(234 5)	1 15 minutes	$\beta, \gamma$
(Uranium) <sub>2</sub>	(234 5)	$2 \times 10^6$ years	$\alpha$
Ionium	230 5	200,000 years	$\alpha$
Radium	226 5	1730 years	$\alpha$
Emanation	223 (222 5)	3 85 days	$\alpha$
Radium A	(218 5)	3 minutes	$\alpha$
Radium B	(214 5)	26 8 minutes	none
Radium C	(214 5)	19 5 minutes	$\alpha, \beta, \gamma$
Radium D	(210 5)	16 5 years	none
Radium E	(210 5)	5 8 days	$\beta$
Polonium	(210 5)	136 days	$\alpha$
? Lead	(206 5)	— •	—

The properties of both radium and its emanation are now quite well known. Radium is a metal of the calcium group, with an atomic weight of 226 5. It has been prepared in a metallic state, and its properties are found to agree with the place we have

assigned to it in the periodic table. The emanation on the other hand is, as we have said, a chemically inert gas resembling the members of the helium group. It can be liquefied at  $-150^{\circ}\text{C}$ . Sir William Ramsay has even succeeded in determining its density, an achievement which as a triumph of skill and refinement of experimental method is beyond all praise. The difficulties of the work will be realised when it is mentioned that the total volume of emanation available for the determination was less than one-tenth of a cubic millimetre.

The molecular weight of the emanation deduced from this determination is 223. Assuming the gas to be mon-atomic like the gases it most resembles, this is also its atomic weight.

What happens to that fragment of the radium atom which represents the difference between 226.5, the atomic weight of radium, and 223, that of its emanation? The answer is not far to seek. It will be remembered that radium is constantly giving off what are known as  $\alpha$ -rays, which, as we saw in an earlier chapter, have been proved to be helium atoms with a high velocity and an electric charge. The atomic weight of helium is 4.0. Within the limits of experimental error this is the difference between the weight of an atom of radium and that of the emanation.

The break-up of the radium atom therefore takes place as follows. For some reason or other, perhaps owing to loss of energy, the nucleus of the radium atom becomes unstable, this instability resulting in the violent expulsion of a helium nucleus from the system. The huge velocity of the  $\alpha$ -particles at first lead to the suggestion that the atom was in rapid rotation, and that the process resulting in the projection of the  $\alpha$ -particle resembled the bursting of a flywheel. This is unnecessary. The mere electrical forces between charged particles so closely packed

as those within an atomic nucleus would be quite sufficient to produce the velocities observed, as indeed we have seen in the case of the collision between the  $\alpha$ -particle and the hydrogen atom. The ejection of the helium nucleus, and consequent decrease in atomic weight of four units enables the residual system to attain a temporary stability, the new element thus formed happening in this particular instance to be gaseous.

The emanation itself is very far from being stable. It is half decomposed in a little less than four days, the new decomposition product being in this case a solid. We cannot follow here the changes undergone by the atom in its attempts to reach a stable state. They are, however, summarised in Table XI, which gives at a glance the whole of the interesting but pitiful story from the break-up of the original uranium atom to that of polonium, the last member of the chain to be definitely identified.

The first column gives the name of the element, and its probable atomic weight. Those enclosed in brackets have not been actually determined, but are deduced on the assumption that each emission of an  $\alpha$ -particle involves a loss of atomic weight of four units. The second column gives the time taken for the element to lose one-half of its mass, or in other words for one-half of its atoms to decompose. It may be called the average life of the atoms of the element. The third column indicates the nature of the rays emitted by the substance on its decomposition.

Polonium itself is radio-active, but its decomposition product has not yet been identified. The worn out atom has probably found peace at last, and hence no longer emits those radiations, which in most cases afford our only means of following its changes. It will be seen from the table that five  $\alpha$ -particles are given out in the passage from radium to this final product. If each of these is a helium

atom the atomic weight of the final element should be  $226.5 - (5 \times 4)$  or  $206.5$ . This is very approximately the atomic weight of lead, and it has been conjectured with some degree of probability that lead is the final stable product of this great series of changes. At present, however, the evidence can hardly be said to amount to a proof.

Most of these radio-active changes, as they are called, result in the expulsion of an  $\alpha$ -particle, and consequent change in atomic weight. Others, however, for example uranium X, give off only  $\beta$ -particles, and hence differ inappreciably in atomic weight from their immediate successor, though differing sufficiently in their chemical properties to enable us to separate them by chemical means. It is found that the loss of a  $\beta$ -particle increases the valency of the atom by unity. On the other hand, the expulsion of an  $\alpha$ -particle reduces the valency by two. This is very well seen in the case of radium and its emanation, radium being a divalent metal of the calcium group, while its emanation is a heavy, chemically inert gas belonging obviously to the helium family. The  $\gamma$ -rays which always accompany  $\beta$ -radiation are merely electro-magnetic pulses due to the sudden ejection of the negatively charged particles, and do not concern us here. In some cases there is apparently no emission of any kind of radiation by the atom, the change in this case consisting of a mere rearrangement of the electrons within the atom itself.

So far we have been treading on safe ground. There can be no doubt that the scheme we have outlined so briefly above represents the true relation between the various radio-active substances. The disintegration theory which is due to the genius of Professor Rutherford, as much of the work embodied in the table is due to his experimental skill and energy, is the only theory which can in any way

explain this novel series of facts. It is now universally accepted. It is when we come to consider the mechanism of the change that difficulties arise.

Of actual knowledge we can hardly be said to have any, but something may be conjectured. In the first place it may be regarded as practically certain that the instability which leads to the dissolution of the atom arises within the nucleus of the atom. We know hardly anything of the constitution of the nucleus except the magnitude of the resultant charge which it carries. In the case of uranium, it amounts to approximately 100 times the charge on an electron, which, in itself, if we are to regard the charge as built up of positive electrons, would make the nucleus sufficiently complex. In addition, however, we have, as explained in Chapter VI, strong grounds for supposing that the nucleus also contains negative electrons, probably in fairly considerable number. At any rate, we may regard it as almost certain that the  $\beta$ -particles, moving as they do with velocities approaching within a few per cent. of the velocity of light, are ejected, like the  $\alpha$ -particles, from the nucleus, as such enormous velocities could hardly be produced by the comparatively weak forces existing between the nucleus and its external electrons.

A study of the series of radio-active changes, indeed, suggests that it is these nuclear electrons, as we may call them, which are the real disturbers of the atomic peace. It may be noticed that, whereas the expulsion of an  $\alpha$ -particle seems to afford little relief to the disturbed atomic system, the expulsion of a  $\beta$ -particle is in every case accompanied by a marked increase in the stability of the system, the change immediately succeeding the ejection of a  $\beta$ -particle occupying a much longer time than those immediately preceding it.

We have seen in Chapter VIII that an electron

revolving in a circle is a source of radiation. The rate of radiation depends on several factors. A single electron moving in a closed orbit of any shape is a very efficient radiator, and would quickly drain any atom of its stock of energy. On the other hand, a large number of electrons moving in the same circle would radiate comparatively feebly.

If we may hazard a guess—and it is nothing more—we may suggest that some of the nuclear electrons, at any rate in the atoms of very high atomic weight, form systems which are only stable so long as the system is rotating at more than a certain speed, in much the same way that the earth is kept from falling into the sun by the speed with which it describes its orbit. This system would, however, necessarily radiate some energy, so that in course of time the speed would fall below that necessary for stability and the system would break up into something simpler—perhaps a ring containing one fewer electron. The election cast out from the ring would obviously disturb the equilibrium of the remainder of the nucleus, and one or more  $\alpha$ -particles are ejected from the nucleus by the forces set up at longer or shorter intervals. At last the emission of these positively charged portions enables the atomic forces to expel the disturbing  $\beta$ -particle, this expulsion being followed by a more or less prolonged lull in the proceedings. Thus in the case of the break-up of the radium atom, four  $\alpha$ -particles are ejected in quick succession, one of the stages lasting only three minutes, until finally radium C expels the disturbing electron, and the succeeding element, radium D, enjoys an average life of sixteen years.

The subject is one full of difficulties, but where so much has been done we may well expect still more. We are marching with a triumphant army, and are not inclined to set any bounds on the extent of our possible conquests in the future.

In addition to the radium-uranium series, two other elements, thorium and actinium, are strongly radio-active, giving rise to series of decomposition products, similar to the chain we have already considered. The question now arises, are all the elements suffering from this slow decay, or are these few heavy elements alone in their spontaneous decomposition?

Extensive researches have been made to answer this question, but the results are perhaps not quite as definite as might be desired. Potassium has been found to give off appreciable quantities of  $\beta$ -radiation, its activity in this respect being about 1% of that of uranium. Its radio-activity, if such it is, seems to be of a peculiar kind, as in spite of very prolonged and drastic experiments, both by Campbell, who discovered the phenomenon, and by others, it has not been found possible to separate from the potassium any substance bearing the same relation to the potassium as uranium X bears to uranium. Rubidium and possibly caesium show similar effects.

With all other elements the effect, if it exists, is very small. There is, however, considerable evidence for the radio-activity of all kinds of matter, although it hardly amounts to a formal proof.

If we examine a quantity of air enclosed in a metal vessel we find that, even in the absence of any specific ionising agent, a certain number of ions are always being formed in the air, which enable us to send a small but measurable current through it. It has been shown that a great part of this ionisation is due to radium, which, disseminated through the atmosphere as emanation, or present in solid form in the soil, seems to be quite ubiquitous. It is found, however, that the amount of this ionisation depends on the substance of which the walls of the vessel are made: it is, for example, greater in a lead than in a copper vessel. This

would certainly seem to point to the emission from the walls themselves of an ionising radiation of some sort, which is greater in amount for lead than for copper

The matter is complicated by the fact that a certain amount of secondary radiation is set up when radium rays impinge on various metals, and these might very well depend for their intensity on the nature of the metal used. Dr N R Campbell, who has made this subject his own, decides against this explanation. I cannot do better than quote his deliberate conclusions

"It has been proved beyond doubt that the emission of ionising radiation is an inherent property of all the metals investigated. It is not of course necessary that this ray emission should be identified at once with radio-activity—if that word is taken to mean a process of ray emission accompanied by atomic decomposition. But the constant intensity of the rays, and the probability that the larger portion of them are  $\alpha$ -rays, afford considerable support for that hypothesis, while I know of no other process which affords any analogy."

The process is not proceeding at such a rate as to give cause for legitimate alarm. As we have seen, the average life of a uranium atom is about five thousand million years, from a comparison of the relative intensities of the radiation from uranium and from ordinary materials we may conclude that the average existence of the latter cannot be less than ten thousand times longer still. If, however, we accept Dr Campbell's conclusion that all substances are emitting  $\alpha$ -particles, then, whether quickly or slowly, all matter is in the process of gradual dissolution into helium, and perhaps hydrogen.

It is curious that in this case the conclusions to be drawn from a sister science, that of astronomical physics, diametrically contradict those which we

have arrived at from a consideration of radio-activity. It is a well-known fact that the very hottest and therefore presumably the newest stars, when examined by the spectroscope, are seen to consist of very little else than hydrogen, helium, and two other elements, the spectra of which have not yet been identified on the earth. Coming to some of the slightly cooler stars fresh elements all of low atomic weight gradually make their appearance, the list increasing, and elements of higher and higher atomic weight coming into existence as cooler and cooler stars are examined. As we have no reason whatever to suppose that the universe was anything save homogeneous in the beginning, we are led to the conclusion that all the elements as we have them on this earth are in reality aggregates of hydrogen, helium, and these two unknown elements.

In these stars progress is obviously from the simple to the complex. Little by little new elements are created by the gradual aggregation of the lighter atoms. On earth, so far as we can follow it, the change is in the opposite direction, the heavier atoms such as uranium and thorium spontaneously breaking down into simpler and simpler systems. It must be remembered that so far as we know the decomposition of the radio-active elements is quite uninfluenced by any change of conditions which can be applied to them. The substance can be heated up in the electric furnace or cooled to the temperature of liquid hydrogen without in any way altering its slow but steady rate of decomposition. It is true that the highest temperatures which we can attain are small compared with those of the hotter stars, but it is difficult to conceive that a rise in temperature should assist aggregation, its tendency being always in the direction of disintegration.

The question suggests itself, are the elements

as we know them merely a part of a great cycle of growth and decay? Is the atom born, to grow old, decay, and die? Are new atoms being formed in the secret places of the universe to take the place of those that have passed away? The facts have been briefly stated above, but of explanation there appears at present to be none. We are brought not for the first time to one of those mysteries which science has so far failed to illuminate.

We have weighed and measured the atom, we have analysed it and learned something of the stuff of which it is made and a little of its inner structure, and the way in which it behaves. We have watched its dissolution and attended its obsequies. Whether it will ever be granted to us to sit as spectators at a new birth time alone can show.

## APPENDICES

### APPENDIX A

(See page 48)

#### DEFLECTION OF THE POSITIVE RAYS BY ELECTRO- STATIC AND MAGNETIC FIELDS.

##### (1) *Electrostatic Deflection*

Let  $d$  be the length of the path of the particles over which the field is applied, and  $D$  the distance of the photographic plate  $Z$  (Fig. 9) from the centre of the field  $MN$ . In the apparatus used  $d$  is small compared with  $D$ .

Since the field is uniform the particle is acted upon by a force  $X E$ , and acquires an acceleration  $X E/m$  in a direction perpendicular to its initial velocity. This acts for the time  $t$  taken by the particle to describe the path  $d$ , that is for a time  $d/v$ . Hence velocity  $v'$  acquired under the action of the field—

$$= \frac{X E}{m} t = \frac{X E}{m} \frac{d}{v}$$

The particle describes the remainder of its path from the field to the plate under these two velocities. Hence the deflection  $x$  is to the horizontal distance travelled  $D$  as the acquired velocity  $v'$  is to the initial velocity  $v$  of the particle. Thus—

$$\frac{x}{D} = \frac{v'}{v} = \frac{X E d}{m v^2}$$

$$x = D - d \frac{XE}{mv^2}$$

(2) *Magnetic Deflection*

The path of the rays in the field is bent into the arc of a circle of radius  $r$  where  $r = \frac{mv}{HE}$

On leaving the field the particles continue to move along the tangent to this circle at the point where the field ends. Hence the angular deflection  $\theta$  of the beam is the angle between the tangents to this circle where the path enters and leaves the field respectively. This is obviously the same as the angle between the normals to the circle at those points.

Hence, if  $d$  is small compared with  $r$ , as is the case in practice, we have—

$$\tan \theta = \frac{d}{r} = d \frac{HE}{mv}$$

But, if  $y$  is the deflection as measured on the photographic plate—

$$\frac{y}{D} = \tan \theta = d \frac{HE}{mv}$$

Hence—

$$y = D - d \frac{HE}{mv}$$

## APPENDIX B

(See page 69)

## ELECTRO-MAGNETIC MASS OF AN ELECTRON

With the electron as centre describe two spheres of radius,  $r$  and  $r + dr$ , and draw two radii making

angles  $\theta$  and  $\theta + d\theta$  with the direction of motion. If these radii are supposed rotated about the direction of motion of the electron, they will sweep out a hollow cone, cutting from the sphere of radius  $r$  a circular zone, the area of which is—

$$2\pi r \sin \theta \cdot r d\theta$$

The volume of the space included between the two spheres and the hollow cone is thus—

$$2\pi r^3 \sin \theta d\theta dr$$

The magnetic field due to the moving electron is obviously constant throughout the annular space so defined and equal to—

$$\frac{ev \sin \theta}{r^2}$$

The energy of the magnetic field in the space is thus—

$$\frac{e^2 v^2 \sin^2 \theta}{8\pi r^4} \cdot 2\pi r^3 \sin \theta d\theta dr, \text{ or } \frac{e^2 v^2 \sin^3 \theta d\theta dr}{4r^2}$$

Hence the total magnetic energy in the space between the two spheres is—

$$\begin{aligned} \int_0^r \frac{e^2 v^2 \sin^3 \theta}{4r^2} dr d\theta &= \frac{e^2 v^2}{4r^2} \times 2 \int_0^{\pi} \sin^3 \theta d\theta \\ &= \frac{1}{3} \frac{e^2 v^2}{r^2} dr \text{ since } \int_0^{\pi} \sin^3 \theta d\theta = \frac{2}{3} \end{aligned}$$

The total energy in the field is therefore the integral of this quantity from the surface of the electron of radius  $a$  to infinity

# INDEX

- $\alpha$ -particle
  - an atom of helium, 39
  - charge on, 35, 38
  - counting the, 35
  - nature of, 39
  - tracks of, 30
- Atom
  - condition of, when emitting light, 143
  - diameter of nucleus, 88
  - mass of hydrogen, 41
  - number of electrons in, 83 *et seq*
  - structure of, 90 *et seq*
- Atomic data, 3, 185
- volume, 109
- Avogadro's constant, 41
- $\beta$ -particle
  - $e/m$  for, 21
  - Kaufmann's experiments on, 76
  - variation of mass with velocity, 70
- Benzene, structural formula, 127
- Cathode rays
  - $e/m$  for, 12 *et seq*
  - from hot oxides, 19
  - tracks of, 31
  - velocity of, 18
- Change of state, 151, 152
- Charge ~~carried~~ by an electron, 27
  - by  $\alpha$ -particle, 35, 38
- Chemical affinity, 112, 122
- Cohesion, 101
- Compounds
  - classes of, 118
  - unsaturated, 116, 128
- Deflection, magnetic and electric
  - of cathode rays, 12, 19
  - of positive rays, 46, 180
- Discharge tube
  - appearance of, 10
  - positive particles in, 42 *et seq*
- Dispersion of light, 107
- $e/m$ , values of, for electrons from different sources, 21
- Electrical conductivity
  - ratio of, to thermal conductivity, 163
  - theory of, 158
- Electrolysis, 113
- Electromagnetic mass, 68 *et seq*, 181
- Electron
  - charge on, 27
  - mass of, 21
  - radius of, 81
  - variation of mass with speed, 75
- Electrons
  - grouping of, in atom, 94 *et seq*
  - number of, in atom, 83 *et seq*
  - light radiating, 132, 138
  - valency, 104
- Emission of heat by radium, 166
- Faraday's theory of light, 132
- Faraday tubes, 71, 130, 131

## Hydrogen

- absorption of light in, 145
- force between atoms in molecule of, 125
- mass of atom of, 41
- spectrum of, 140

$H_2$  in discharge tube, 58

- structural formula, 126

Heat, dynamical theory of, 150

- conduction of, 161
- emitted by radium, 166

Intra-molecular ionisation, 118

Ionisation of gases, 22

Kinetic theory of gases, 4, 154

## Mass

- electromagnetic origin of, 68
- et seq*, 88, 181

Molecule, radius of, 3, 157

## Molecules

- motion of, in solids and liquids, 151, 152
- number of, in 1 c.c. of gas, 3, 41

## Number

- of electrons in atom, 83 *et seq*
- of molecules in gas, 3, 41

Periodic classification of elements, 98, 111

Periodic orbits, 147

Positive particle, *see*  $\alpha$  particle

## Positive rays

- charge on, 42, 56, 60
- deflexion of, 48, 180, 181
- electrical measurement of number of particles in, 64
- m/s* for, 52 *et seq*
- nature of, 51
- production of, 45

Potassium, emission of  $\beta$  rays from, 176

Radioactive disintegration of uranium, 169

Radioactive disintegration of radium, 169

- causes of, 174
- products of, 170

Radioactivity of ordinary materials, 176

## Radium emanation

- molecular weight, 171
- production and decay of, 169

Rontgen rays, track of a beam of, 31

Selective absorption of light, 143

Spectra

- nature of particles producing, 138
- of stars, 178
- production of, 146

Specific electric induction, 120

Spectrum series, 139

Structural formulae, 126, 127

## Thermal conductivity

- relation to electrical conductivity, 163
- theory of, 161, 164

Unsaturated compounds, 116, 128

Uranium, disintegration of, 167, 170

## Valency

- electrical theory of, 112 *et seq*, 118
- electrons, 104, 106, 107

## Valencies

- Abegg's table of, 116
- positive and negative, 116

Van der Waal's equation, 155

Water vapour, condensation on charged particles, 23, 30

X rays, track of ~~beam~~ of, 31

Zeeman effect, 134, 183
